Osteoporotic hip fracture

Cardiac biomarkers

Major adverse cardio-vascular events

ABSTRACT

Osteoporotic hip fracture (OHF) is an increasingly frequent age-related pathology, which results in high rates of functional loss and mortality within the first year after surgery. This study assessed whether preoperative levels of brain natriuretic peptide (NT-proBNP) and troponin I were related to early occurrence (30d) of major adverse cardio-vascular events (MACE) after OHF repair surgery. During a 6-month period, perioperative clinical and analytical data from consecutive patients, without known history of cardiovascular disease and undergoing surgery for OHF repair at a single centre, were prospectively collected. MACE was defined as acute myocardial ischaemia or infarction, acute heart failure or cardiovascular death. amongst the 140 patients included, 23 (16.4%) developed postoperative MACE (MACE group) and 117 did not (Control group). Compared to those from control group, patients from MACE group were older, had poorer physical status (ASA III–IV), received preoperative red blood cell transfusion (RBCT) more frequently, presented with lower haemoglobin concentrations and higher NT-proBNP, creatinine and troponin I concentrations. Overall, RBCT requirements and 30d mortality rate were also higher in MACE group. However, in multivariate analysis, only preoperative RBCT, creatinine >1 mg/dL and NT-proBNP >450 pg/mL remained as independent preoperative risks factors for postoperative MACE, while 95% confidence intervals of odds ratios were wide. Though our findings require confirmation in a larger multicentre cohort, identifying risk factors for early postoperative MACE after OHF repair surgery, might facilitate assessing patients' risk prior to and following surgery, and targeting them the appropriate preventive and/or therapeutic interventions.

Introduction

The osteoporotic hip fracture (OHF) is an increasingly frequent age-related pathology, which results in high rates of irreversible functional loss and mortality within the first year after surgery [1–8]. A recent retrospective epidemiological study estimated an overall incidence of 517 cases per 100,000 elderly people per year in Spain [9], whereas a prospective multicentre study reported a 15.8% overall mortality rate (24.1% in men, 13.4% in women) within the first year, with 53% of deaths occurring within the first 3

months [10]. Most common causes of death after OHF were respiratory and cardio-vascular complications; the latter being aggravated the presence of postoperative anaemia [11].

Given the frequency of postoperative cardiac complications in OHF, there is an increasing interest in finding preoperative biomarkers that may identify patients at risk. These biomarkers include cardiac troponins and natriuretic peptides. In clinical practice, cardiac troponins I and T (as markers of myocardial damage) are mainly used in the diagnosis of acute coronary syndrome, while the brain natriuretic peptides (BNP) (as markers of myocardial stress or myocardial stretch) are mainly used for diagnosing and grading the severity of heart failure [12–14].

Regarding OHF, several studies have shown that preoperative elevations of troponin I [15,16] or T [17,18] are predictors of postoperative morbidity and mortality in these patients' populations. Similarly, there are several studies evaluating the role of

List of abbreviations

OHF:	Osteoporotic hip fracture
BNP:	Brain natriuretic peptide
MACE:	Major adverse cardio-vascular events
ASA:	American Society of Anesthesiologists
RBCT:	Red blood cell transfusion
NT-proBNP:	N-terminal fragment of pro-BNP
PHF:	Pertrochanteric hip fracture
SHF:	Subcapital hip fracture

preoperative brain natriuretic peptide assessment (especially the N-terminal fragment of pro-BNP [NT-proBNP]), either alone [19,21] or in combination with troponin I determination [22], as a predictor of cardiovascular events in this type of surgery. It has been suggested that NT-proBNP assessment is more reliable than American Society of Anaesthesia (ASA) physical status scale scores for predicting postoperative cardiac complications [23].

However, though the association between elevated preoperative levels of cardiac biomarkers and postoperative cardiovascular complications seemed to be strong, most published studies included mixed populations of OHF patients presenting with or without cardiovascular co-morbidity. Thus, the primary objective of this prospective study was testing the hypothesis that preoperative levels of NT-proBNP and Troponin I may be useful for predicting the occurrence of major postoperative adverse cardiovascular events (MACE: acute myocardial ischaemia or infarction, acute heart failure or cardiovascular death) in OHF patients without known cardiovascular pathology. The possible relationship between MACE and other risk factors such as anaemia or red blood cell transfusion (RBCT) were secondary objectives.

Methods

Study design

A prospective study of consecutive patients undergoing surgery for osteoporotic subcapital (SHF) or pertrochanteric (PHF) hip fracture repair at our Centre during a 6-month period was conducted. Upon preoperative admission, the attending orthopaedic surgeon requested the laboratory tests (see below) and patients were screened for eligibility and enrolment by a cardiologist (AA). The study was reviewed, approved and registered by the Committee of Research Ethics of the Autonomous Community of Aragón, Spain (C.P. IACS 81/011-C.I. PI 08/77). All patients or their authorised relatives signed informed consent to enter the study.

Inclusion criteria

Only patients without a known history of cardiovascular disease, sustaining an OHF due to low-energy trauma, defined as ground level falls up to two levels of stair height [24], and undergoing repair surgery were included. Patients with incomplete data sets for the studied outcomes were also excluded from the analysis.

Perioperative management

All patients were operated on by the same surgical team, under standardised anaesthesia, antibiotic prophylaxis, and postoperative analgesia. Surgery was scheduled during standard daytime working hours (Monday to Friday), whenever medical staff, operating

theatre or blood were available, and if the patient's medical condition allowed it. Neither normovolaemic haemodilution or perioperative cell salvage nor antifibrinolytic drugs were used in any patient. A Gamma 3 trochanteric nail (Stryker Trauma GmbH, Germany) was inserted for fixing PHF, and a cemented hemiarthroplasty (Furlong JRI Orthopaedics, U.K.) or an uncemented total hip arthroplasty (ABG-II, Stryker, USA) for SHF [25].

All patients received closed-suction drains, usually two, which were placed after wound closure and removed the next morning after the operation. The postoperative blood loss in the vacuum collectors was recorded. All stayed in the post-anaesthesia recovery unit for at least 4 h before being transferred to the ward.

During hospitalization, they were clinically evaluated daily, and full laboratory evaluation was performed preoperatively and at postoperative day 7. After discharge, they attended a follow-up visit for clinical and laboratory evaluation at postoperative day 30.

Wherever possible, all patients were allowed to sit on the edge of the bed within the first 24 h, and were transferred to a chair during the second postoperative day. Patients were encouraged to stand up, supervised by a physiotherapist, starting then partial weight bearing with walking aids as tolerated, usually at the 3–4 postoperative day. In the case of PHF considered to be unstable (e.g., comminuted postero-lateral femoral fracture), weight bearing was delayed for 4–6 weeks.

Thrombo-prophylaxis was provided by once-daily, weight-adjusted dosing of low molecular weight heparin (Enoxaparin, Clexane, Sanofi-Aventis S.A., Barcelona, Spain), which was started 12 h after surgery and maintained for the first 30 postoperative days.

Stimulation of erythropoiesis

Unless there were contraindications, patients received: (1) IV iron (200 mg, Venofer, Vifor, Saint Gallen, Switzerland), three doses starting on admission; (2) Vitamin B₁₂ (1 mg) intramuscularly on admission; and (3) Folic acid (5 mg/day) for the entire duration of hospitalization. Patients presenting with preoperative haemoglobin levels <13 g/dL also received a single dose of recombinant human erythropoietin (40,000 IU, sc; Eprex, Janssen-Cilag, Madrid, Spain) 24 h after admission [25].

Transfusion protocol

The anaesthesiologist made decisions on transfusion, both in the operating theatre and in the anaesthesia recovery unit. On the ward, measurement of postoperative blood loss and decisions on postoperative transfusions were made by the attending surgeon. In these orthopaedic patients, transfusion was considered when the patient had symptoms of acute anaemia (hypotension, tachycardia, tachypnoea, dizziness, fatigue, etc.), or their haemoglobin level felt below 8 g/dL [25].

Data collection

A set of demographic and clinical data was prospectively gathered for all patients, including sex, age, ASA physical status scale, type of OHF, co-morbidities (arterial hypertension, diabetes mellitus, dyslipidaemia), surgical procedure (anaesthesia, duration, type of fracture fixation, drain output), RBCT rate (percentage of transfused patients) and index (RBCT units per patient), occurrence of MACE (myocardial infarction [26], acute cardiac failure [27] and /or cardiovascular mortality) (primary outcome measure), and overall mortality within 30d postoperatively.

Perioperative laboratory tests were performed in blood samples drawn preoperatively (upon hospital admission) and at postoperative days (POD) 7 and 30, and included: haemoglobin (DXH-800, Beckman Coulter, Brea, CA, USA), iron status and creatinine (AU-5800, Beckman Coulter), troponin I (Unicel DXI 800, Beckman Coulter), NT-proBNP (Cobas 411, Roche Diagnostic, Mannheim, Germany). Additionally, Hb concentration was assessed at POD 1 and at any time during hospitalisation, should it be deemed necessary by the attending physician. Anaemia was defined by haemoglobin <13 g/dL [28–30], irrespective of gender, and ID by TSAT <20% and/or ferritin <100 ng/mL [29].

Statistical analysis

As all patients without a known history of cardiovascular disease who underwent surgery for OHF repair during a 6-month period were included in the analysis, the study sample size was not calculated beforehand. Overall, 69 out of 140 patients presented with serum NT-proBNP concentrations >450 pg/mL. Of those, 19 out of 23 (83%) were in the MACE group and 50 out of 117 (43%) in the control group. In a post-hoc calculation, the actual size of the study sample provides an alpha error of 0.037 and a statistical power of 0.958.

Data were expressed as percentages or as the mean \pm standard deviation or median [interquartile range]. Pearson's chi-square test or Fisher's exact test was used for comparison of qualitative variables. Parametric two-way analyses of variance or non-parametric Mann–Whitney *U* test were used for comparison of quantitative variables, after consideration of distributional characteristics.

Variables with significant differences between groups were introduced in the multivariate analysis (multinomial logistic regression), with MACE as the dependant variable and continuous variables being dichotomised. Established cut-off was used for troponin I (>0.03 μ g/L) [31]. To identify the preoperative NT-proBNP and creatinine cut-off values for predicting the occurrence of postoperative MACE, according to its sensitivity and specificity, the receiver operating characteristic (ROC) curve was used and the area under the curve (AUC) was calculated. For variables showing high collinearity (Pearson's correlation coefficient >0.7), only one of them was introduced in the multivariate analysis.

All statistical analysis were performed with computer software (IBM SPSS 24.0, Chicago, IL), and a *p* value of less than 0.05 was considered significant.

Results

A total of 209 patients sustaining OHF (140 PHF, 69 SHF) were admitted to our institution during the 6-month study period. Sixty-seven of them were excluded: 7 treated conservatively and 60 because of a previous history of cardiovascular disease. Additionally, two patients were missed during follow-up (incomplete data). Amongst the remaining 140 (91 PHF, 49 SHF), 23 (16.4%) developed MACE within 30d postoperatively (MACE group) and 117 did not (Control group).

Demographic, clinical and analytical characteristics are depicted in Tables 1 and 2, and Fig. 1. Preoperatively, patients from MACE group were older ($p = 0.053$), had poorer physical status (ASA III–IV) ($p = 0.022$) and received RBCT more frequently ($p = 0.001$), compared to those from control group (Table 1). There were also differences in their analytical parameters. Compared to control group, perioperative haemoglobin concentrations were lower in MACE group ($p = 0.001$), without differences in ferritin or TSAT levels or ID prevalence (Table 2, Fig. 1A–C), whereas NT-proBNP levels were higher (Table 2, Fig. 1D) ($p = 0.001$). Similarly, higher preoperative creatinine ($p = 0.001$) and troponin concentrations ($p = 0.02$) were observed in MACE group, compared to control

MACE, major adverse cardiovascular event; NT-proBNP, N-terminal fragment of type B natriuretic peptide; TSAT, transferrin saturation; Iron deficiency: ferritin < 100 ng/mL and/or TSAT <20%. Data are mean \pm standard deviation or median [interquartile range].

group (Table 2). Overall, RBCT rate and index during hospitalisation ($p = 0.001$) and 30d mortality rate ($p = 0.001$) were also higher in the MACE group ($p =$ Table 1).

To ascertain whether the preoperative variables associated with postoperative MACE in the univariate analysis remained as independent risk factors in a multivariate analysis, they were introduced into a multinomial logistic regression model as dichotomised variables (Yes/no: ASA III–IV, preoperative RBCT, creatinine >1 mg/dL, troponin >0.03 μ g/L, NT-proBNP >450 pg/mL). For NT-proBNP, cut-off level was established at 450 pg/mL because the ROC curve offered an AUC of 0.773 [0.654–0.893] (sensitivity, 83%; specificity, 54%) (Fig. 2A). For creatinine, the cut-off level was established in 1 mg/dL, which is commonly used in clinical practice (sensitivity, 52%; specificity, 78%), and was derived from a ROC curve with an AUC of 0.705 [0.654–0.826] (Fig. 2B). The cut-off level for troponin was obtained from the literature (24). As depicted in Table 3, in the multivariate analysis, only preoperative RBCT ($p = 0.009$), creatinine >1 mg/dL ($p = 0.036$) and NT-proBNP >450 pg/mL ($p = 0.043$) remained as independent risks factors associated with the occurrence of postoperative MACE.

Discussion

Respiratory and cardio-vascular complications are the most common causes of death after OHF [11]. This study found that preoperative NT-proBNP concentration >450 pg/mL, preoperative creatinine concentration >1 mg/dL and preoperative RBCT were independently associated with an increased odd ratio (OR) for the occurrence of early postoperative major adverse cardiovascular events (MACE), though 95% confidence intervals [95%CI] were wide (Table 3). These findings are not completely new [19–23] but, as far as we know, this is the first study documenting a statistically independent association exclusively in a population of OHF patients without a known history of preoperative cardiovascular co-morbidity.

Hip fracture patients presenting with high (>2370 ng/L) or intermediate (806–2370 ng/L) preoperative NT-proBNP concentration has been reported to have higher short-term postoperative mortality (<30 days), compared to those with low NT-proBNP concentration (<806 ng/mL) (15% vs. 11% vs. 2%; $p = 0.04$) [12]. Similar cut-offs of NT-proBNP have been reported by Chong et al. [32,33] for in-hospital cardiac events and 1- and 2-year mortality. However, in these studies, up to 70% of patients included presented with a history of cardiovascular disease, and were expected to have high rates of postoperative cardiovascular complications. More recently, in a series of 328 OHF, the cut-off level of NT-proBNP for predicting postoperative cardiovascular complications, as determined by ROC curve analysis (AUC 0.87 [95% CI, 0.80–0.94]; $p < 0.001$), was 600 pg/mL, with a sensitivity, specificity, positive predictive value, and negative predictive value of 79%, 81%, 25%, and 98%, respectively [21]. Though this cut-off was lower than those previously reported [25,26], again 38% of OHF patients presented with preoperative cardiovascular co-morbidity. The present study included only patients without a known history of cardiovascular disease, so it is not surprising that an even lower the cut-off level of NT-proBNP (450 pg/mL) was found. This lower cut-off might be reflecting a non-clinically apparent cardiac disease.

Preoperative RBCT was the stronger independent risk factor for postoperative MACE (Table 3). Amongst patients developing MACE, admission Hb levels were significantly lower in those receiving preoperative transfusion compare to those who did not (9.3 ± 2.7 g/dL vs. 12.7 ± 1.4 g/dL, respectively; $p < 0.001$). This suggests the presence of chronic anaemia in this patient subpopulation, in which several compensatory mechanisms may have been

activated to improve the tolerance of anaemia. However, many anaesthesiologists are still reluctant to anaesthetize patients presenting with preoperative Hb < 10 g/dL. This reluctance prompts the administration of RBCT before taking them to the theatre. The transfused blood is not saturated with oxygen as it enters the circulation and might not confer an immediate positive effect on oxygen delivery (as its oxygen downloading capacity is limited by low 2,3DPG concentrations) [34], while it has an immediate impact on circulatory volume, viscosity and rheological characteristics of recipient's blood (especially in patients with even mild kidney disease). This can lead to various positive and negative changes in macro- and micro-circulation (e.g. transfusion-associated circulatory overload, reduced cardiac output, or improved microcirculation) [35,36], which might be enhanced by subsequent intra- and/or postoperative RBCTs (Table 1). Another issue is the change in left ventricular geometry developed in chronic anaemia (such as ventricular hypertrophy) which might be aggravated with RBCT [37].

Iron deficiency, which was very frequent in the study population (54%, Table 2), may precipitate heart failure [38], which was the cause of death in most cases. As depicted in Table 2, there was a trend towards higher prevalence of iron deficiency in the MACE group compared to the control group. However, as all patients received 600 mg IV iron sucrose perioperatively, the possible role of ID in postoperative heart failure and 30-day mortality is difficult to establish. Three randomized trials provide support for the beneficial effects of intravenous iron in patients with heart failure [39], though data from large, independent, and more extended studies are needed [40]. Additionally, the mechanisms underlying non-erythropoietic effects of rHuEPO, such as neurological and renal protective effects, and IV iron, such as improvement of heart function, need to be elucidated [41,42].

This study presents some limitations. First, this is a single-centre study and, though this ensured uniform patient care, including aggressive perioperative erythropoiesis management, applicability of the study's findings to other centres might be limited. Second, the whole study sample is relatively small, the follow-up time short. Thus, NT-proBNP assessment might have an important role for the patient whose past history or a reliable exam cannot be obtained. However, confirmation in a larger cohort with a longer follow-up is needed. Third, the absence of a documented history of cardiovascular disease does not exclude conclusively its existence, especially if demographic characteristics and comorbidity of the

study population are taken into consideration. Thus, apart from the preoperative electrocardiogram, the selection of patients without previous cardiovascular disease could be optimised implementing a non-invasive diagnostic image-based test (echocardiogram), without delaying the procedure, thanks to the coordinated efforts of the Hip Fracture Unit multidisciplinary staff (cardiologist, internist, orthopaedic surgeon, physiotherapist, and anaesthetist). Four, in our series time-to-surgery is clearly over all the international recommendations (with a clear limit established in 48 h). However, we did not find differences between patients having surgery within 48 h and those operated on after 48 h, regarding the incidence of postoperative MACE (9/42 vs. 14/98; $p = 0.342$) or 30-days mortality (2/42 vs. 7/98, respectively; $p = 0.724$).

In conclusion, despite the above-mentioned limitations, it seems that our data could be useful for everyday clinical practice. Though more research is needed, by identifying significant risk factors associated with early postoperative MACE, the orthopaedic surgeons will be better equipped to assess patients' risk prior to and following surgery, and for targeting them the appropriate preventive or therapeutic interventions.
