The Tamus clade currently comprises two species (Wilkin et al., 2005): D. communis, distributed throughout the Mediterranean Basin and the Macaronesian Islands (Canary Islands and Madeira), and with infraspecific variation in 2.5 ploidy (Viruel et al., 2019); and D. orientalis, restricted to Lebanon and Israel. However, like in many Dioscorea clades (Viruel et al., 2010), the Tamus clade has had multiple previous taxonomic circumscriptions. Based on their berry fruits, the Tamus clade was considered as a separate genus. 2.10 Tamus, distinct from Dioscorea, until 2002 (Caddick et al., 2002). The latter study unified several previously recognized genera (Epipetrum, Nanarepenta, Rajania, Testudinaria and Borderea) to maintain the monophyly of Dioscorea. Moreover, fruits with different degrees of fleshiness have 2.15 been observed in other *Dioscorea* species (e.g. *D. ovinala*, *D.* antaly; Caddick et al., 2002).

> Linnaeus (1753) recognized two species: T. communis, with cordate leaves and a Mediterranean distribution, and T. cretica, with trilobed leaves and typified with material from the Greek island of Crete. In the 19th and early 20th centuries, four Macaronesian endemic species were described (T. edulis, T. parviflora, T. norsa and T. canariensis), while T. cirrhosa, T. cordifolia and T. racemosa were treated as distinct Mediterranean species. In the late 20th century, T. cretica was placed as a subspecies in T. communis (T. communis subsp. cretica, and T. communis f. subtriloba was described as a variety with trilobed leaves found in the Balearic Islands and north-eastern Spain (Catalonia). All these names were subsequently united under the currently accepted D. communis (Caddick et al., 2002); however, this decision was not supported by phylogenetic or morphological data. The second species currently recognized in the Tamus clade, D. orientalis, was originally described as *T. orientalis*, named after its eastern Mediterranean distribution.

> From the above, it is clear that species concepts have undergone many changes since Linnaeus described two Tamus species using morphology, especially reproductive traits (De Queiroz, 2007). As for many other species in other plant genera and families, integrative taxonomic and systematic approaches combining genetic data, morphometrics and climatic envelope data have successfully helped to delimit species in challenging groups of plants (e.g. Frajman et al., 2019). The emergence of high-throughput sequencing (HTS) techniques and the production of thousands of molecular markers have massively increased our ability to resolve relationships between and within species, and subsequently redefine species boundaries (e.g. Fay et al., 2019; Escudero et al., 2020). Among these HTS methods, Hyb-Seq has become widely adopted across plant phylogenomic studies due to its ability to generate data from degraded herbarium materials (e.g. Brewer et al., 2019; Viruel et al., 2019) and to resolve relationships at different taxonomic scales (e.g. Villaverde et al., 2018). Hyb-Seq techniques rely on genome skim data and target capture probes designed either specifically for some genera or families (e.g. Soto Gomez et al., 2019) or more widely across larger groups, including all angiosperms (e.g. Johnson et al., 2019). In this study, we use a multidisciplinary approach combining genomic, morphometric and environmental niche modelling data generated from herbarium specimens to identify taxon boundaries in the

challenging Tamus clade of *Dioscorea*, and to explore their phylogeographic patterns across the Mediterranean.

MATERIALS AND METHODS

Plant material

Seventy-six herbarium specimens identified as Dioscorea communis or D. orientalis were used to obtain genomic, spatial and morphometric data. They were selected as being representative of the macromorphological diversity and geographic distribution ranges of the two species as currently circumscribed (Supplementary Data Table S1). The genomic sampling also included material that was used as outgroup taxa, comprising the two species from the Borderea clade (D. chouardii and D. pyrenaica), which is sister to the Tamus clade (Viruel et al., 2016), and two members of the more distantly related African clade (D. elephantipes and D. sylvatica).

Phylogenomics

Total genomic DNA was extracted from herbarium specimens using a modified CTAB protocol (Doyle and Doyle, 1987). Nuclear target enrichment was used to capture 260 low- to single-copy nuclear (LSCN) genes using RNA baits designed for Dioscorea (Soto Gomez et al., 2019). Genomic libraries were prepared using the NEBNext® UltraTM II DNA Library Prep Kit for Illumina® (New England Biolabs, Ipswich, MA, USA) with AMPure XP magnetic beads and NEBNext® Multiplex Oligos for Illumina® (Dual Index Primer Sets I and II) as tags for simultaneous sequencing. Subsequently, the enriched libraries were multiplexed and sequenced on a HiSeq X platform (Illumina) lane.

We filtered raw paired-end reads by removing adapter sequences and low-quality reads using Trimmomatic v.0.36 (Bolger et al., 2014). We used HybPiper v.1.3.1 (Johnson et al., 2016) to recover 260 nuclear genes and associated introns (Soto Gomez et al., 2019) using sequence data from the transcriptome of D. communis (SRA SAMN11290810) as a reference file following Viruel et al. (2019). We used nQuire (Weiß et al., 2018) to calculate the number of read counts for each allele per single-nucleotide polymorphism (SNP), and estimated the median value of allelic ratios per sample to classify each individual as diploid (<2) or polyploid (>2) as described and optimized for Dioscorea in Viruel et al. (2019). The percentage of polymorphic sites was calculated as the percentage of SNP positions compared with the total number of base pairs retrieved for each sample. Plastome data were recovered using HybPiper and the plastome of D. elephantipes as reference (GenBank NC_009601).

Sequences were aligned with MAFFT v.7 (Katoh et al., 2002) using the --auto parameter, and debugged with trimAl v.1.4.1 (Capella-Gutiérrez et al., 2009) using the -automated1 command. Phylogenomic trees were reconstructed using the concatenated and partitioned nuclear DNA (nDNA) and plastid DNA (pDNA) datasets independently, and for each nuclear gene independently, using maximum likelihood analysis as implemented in RAxML-NG (Katoh et al., 2019) and IQ-TREE 2.70

(Nguyen et al., 2015), with a GTR+GAMMA substitution model and 1000 bootstrap replicates. We used ASTRAL-III (Zhang et al., 2018) to construct a species tree based on the independent nuclear gene trees, and SVDquartets to evaluate 10 000 000 random quartets (or all possible quartets if lower) and 10 000 bootstrap replicates, as implemented in PAUP* 4.0a146 (Swofford, 2002). Haplotype networks were reconstructed with plastid data using the TCS method as implemented in Popart v.1.7 (Clement et al., 2002; Leigh and Bryant, 2015).

We used Structure (Pritchard et al., 2000) to further investigate the genetic clusters within and between taxa based on filtered SNP data from the concatenated nDNA dataset. We tested one to six genetic groups (K = 1-6) allowing admixture at individual level, and correlated allele frequencies, by running five replicates with a 100 000 burn-in and a chain length of 1 000 000 simulations each. Structure Harvester (Earl and vonHoldt, 2012) was used to obtain likelihood values for the multiple values of K and to apply the ΔK criterion to select the optimal K. We plotted Structure results for each K value using StructuRly (Criscuolo and Angelini, 2020).

Divergence times were estimated using a Bayesian relaxedclock approach implemented in BEAST 1.10.4 (Drummond and Rambaut, 2007) and a penalized likelihood approach as implemented in treePL (Smith and O'Meara, 2012) using the concatenated nDNA dataset containing one representative per taxon. In both analyses, the crown node of the African/Mediterranean clade was used as calibration by applying a minimum age of 24 million years (MY) and a maximum age of 40 MY, based on the age estimates from Viruel et al. (2016; 95% highest posterior density interval of 24.3469–39.2223 MY). In BEAST analysis, we applied the GTR+I+G substitution model, Yule tree prior, and an uncorrelated lognormal molecular clock and ran the analysis for 1 billion generations, sampling every 100 000 generations. Convergence and mixing of the Monte Carlo Markov chain in BEAST analysis was assessed using the effective sampling size (ESS > 200) criterion in TRACER v.1.7.1, and all parameters showed ESS values >200. The treePL analysis was conducted in two consecutive runs: (1) applying the 'prime' option to select the most optimal parameter values; and (2) a 'thorough' analysis by setting opt = 1, optad = 2 and optcvad

Spatial analysis 3.45

Occurrence records were obtained from 287 observations from the Global Biodiversity Information Facility (211 occurrences validated by morphology; http://www.gbif.org/) and data from herbarium specimens (76 occurrences). For modelling purposes, the dataset was reduced to keep only georeferenced data.

We used environmental niche modelling (ENM) approaches to reconstruct the potential distribution of the four main clades uncovered in the phylogenomic analyses (see the Results section) under current and past climatic conditions using the maximum entropy algorithm implemented in the R package 'Maxent' (Phillips, 2021). Nineteen bioclimatic variables were extracted from the Bioclim dataset, provided by WorldClim 1.4 in a GIS-based raster format (2.5-min resolution). The correlations between environmental variables were determined with

a Pearson's correlation matrix and subsequent realization of a dendrogram cluster for its visualization (Supplementary Data Fig. S1). We selected a different set of uncorrelated variables for each geographic region with a high percentage contribution (PC): bio4 (temperature seasonality), bio8 (mean temperature 3.65 of wettest quarter), bio9 (mean temperature of driest quarter), bio15 (precipitation seasonality) and bio16 (precipitation of wettest quarter) for the circum-Mediterranean region; bio3 (isothermality), bio6 (min temperature of coldest month), bio8 (mean temperature of wettest quarter), bio14 (precipitation of 3.70 driest month), bio15 (precipitation seasonality) and bio16 (precipitation of wettest quarter) for the Eastern Mediterranean region; and bio3 (isothermality), bio4 (temperature seasonality), bio16 (precipitation of wettest quarter) and bio18 (precipitation of warmest quarter) for the Macaronesian region. The ENM 3.75 analyses were carried out under current climatic conditions, and projected to climatic conditions of the Mid Holocene (MH, ~6000 years ago), the Last Glacial Maximum (LGM, ~22 000 years ago; Braconnot et al., 2007) and the Last Interglacial (LIG, ~120 000 140 000 years BP; Otto-Bliesner et al., 2006) using 3.80 the palaeoclimatic Community Climate System Model (CCSM; Gent et al., 2011). Layers were cropped to represent the distribution range of each phylogenetic group (i.e. DC1, DC2 and DC3 for *D. communis*, and *D. orientalis*; see Results section) to maximize the reliability of the results and discard false oc- 3.85 currences using the package 'raster' (v.3.5-15; R v.4.0.5). We used the Schoener's D and Hellinger's I indices as implemented in ENMtools v.1.0.4 to evaluate niche overlap (Warren et al., 2008, 2010). Equivalence and similarity tests with 1000 replicates were carried out to assess if the overlap between ENMs is 3.90 higher than expected under randomized ENMs.

A multivariate ordination analysis (principal component analysis, PCA) was carried out using uncorrelated bioclimatic variables obtained from WorldClim using the packages 'ade4', 'factoextra', 'magrittr', 'dismo' and 'HH' in R v.4.0.5. 3.95 The correlation analysis was performed with a Pearson correlation matrix and subsequent visualization and selection of variables using a dendrogram cluster. The following ten uncorrelated variables with the highest contribution to the PCA were selected: bio1 (annual mean temperature), bio2 (mean diurnal 3.100 range), bio3 (isothermality), bio7 (temperature annual range), bio8 (mean temperature of wettest quarter), bio9 (mean temperature of driest quarter), bio10 (mean temperature of warmest quarter), bio12 (annual precipitation), bio15 (precipitation seasonality) and bio19 (precipitation of coldest quarter). 3.105

Morphometrics

We studied vegetative and reproductive traits of 76 herbarium specimens (60 males and 16 females), previously used to delimit taxa boundaries in other Dioscorea species (e.g. Viruel et al., 2010), using a 150-mm calliper, a stereomicroscope and ImageJ 1.52a (Schneider et al., 2012). Traits were measured and treated independently for male and female individuals (Supplementary Data Table S2). Pollen grains were sputtercoated with platinum and examined using a Hitachi S4700 cold field emission scanning electron microscope at 2 kV (Hitachi High-Tech Corporation, Tokyo, Japan).

A Pearson correlation of >0.7 was used as a threshold to exclude correlated variables from the analysis. The normality

Kolmogorov–Smirnov test with Lilliefors correction and Levene's test for homoscedasticity were applied to the variables following a normal distribution. Subsequently, comparisons among taxonomic units identified in phylogenomic analyses (see the Results section) were conducted using Kruskal–Wallis and Bonferroni *post hoc* tests. Statistical analyses were performed using the 'nortest', 'Hmisc', 'corrplot', 'PerformanceAnalytics' and 'car' packages in in R v.4.0.5 (R Core Team, 2022).

RESULTS

Data recovery and phylogenomic results

Target capture data recovery for 76 samples of the Tamus clade of *Dioscorea* and the four outgroup samples included in this study are summarized in Table 1. Sequence data are available in the SRA repository: PRJNA525269 and PRJNA895370. An average of 2 240 287 quality filtered paired-end reads were retrieved per sample, ranging between 43 612 and 16 196 619 reads. While the samples from herbarium specimens dated from 1788 to recently collected material, the differences in number of retrieved reads were not related to the age of the specimens. On average, the proportion of reads on target (enrichment efficiency) was 0.33 (0.09–0.60), and although sequences were assigned on average to 258 genes per sample, assemblies at 50 % of the expected size of each gene were retrieved on average for 215 genes per sample.

Our target capture approach allowed us to recover an average of 326 149 bp (45 171–394 977) of nuclear data per sample, which corresponds to a recovery rate of 76.9 % (10.6–93.1 %), while the off-target reads contained plastid data that permitted the assembly of 131 543 bp on average (30 666–151 239) of the plastome per sample. No differences were observed in recovery rates between the clades reconstructed in our analysis (see below); the overall sequencing and target capture data obtained for the four outgroup samples were in the range of the remaining samples.

Both nuclear- and plastid-based phylogenomic reconstructions support the monophyly of the Tamus clade in Dioscorea (Fig. 1), with two highly supported clades that corresponded to the two currently recognized species (D. communis and D. orientalis). Three highly supported subclades were reconstructed in the D. communis s.l. clade in the nuclear tree (Fig. 1). A first split separated the samples of D. communis from Macaronesia (clade DC1). The remaining samples of *D. communis* fell into two sister subclades corresponding to samples of D. communis from the eastern Mediterranean (clade DC2) and Mediterranean and Europe (clade DC3), respectively. Clade DC3 was subsequently further subdivided into (eastern Mediterranean, (central Mediterranean, western Europe)) subclades. Overall bootstrap support was >90 % for most of the nodes (Fig. 1). This phylogenetic tropology was congruent with the reconstructions obtained with ASTRAL-III (Supplementary Data Fig. S2A) and SVDquartets (Supplementary Data Fig. S2B).

The plastid tree was generally congruent with the nuclear tree. However, the plastid topology differed in the resolution of the most recent Mediterranean subclades. In addition, one DC2 sample (R32) was placed in a different subclade (Fig. 1). The remaining Mediterranean *D. communis* samples (DC3) were intermingled in three plastid subclades (I, II and III in Fig. 1). In

the nuclear tree, subclade DC3 from the eastern Mediterranean contained samples with plastid haplotypes from all plastid subclades (I, II and III), and the subclades of DC3 from central Mediterranean and western Europe contained samples with those from plastid subclades I and II, and II and III, respectively (Fig. 1). These subclades were also represented in the haplotype network (Supplementary Data Fig. S2C).

To better understand the source of topological incongruence between the nuclear and plastid phylogenetic trees of the Mediterranean samples of D. communis, we used Structure to investigate whether introgression between samples from different subclades may have occurred. The highest ΔK value (15821.9) was obtained for K = 3 genetic groups (Supplementary Data Fig. S3). All samples in clade DC2 of *D. communis* showed genetic profiles corresponding to one genetic group (Cluster 1), and five samples also showed a percentage of membership <20 in Cluster 2 (i.e. samples R16, R17, S69 and S70) or Cluster 3 (sample R32, 26 %). The samples of *D. communis* in clade DC3 showed genetic profiles corresponding predominantly to Cluster 3 and multiple patterns of admixture with Clusters 1 and 2 (Fig. 2). The genetic profile of one DC3 sample from the eastern Mediterranean subclade showed a percentage of membership >20 in Cluster 1, and nine DC3 samples had membership percentages of >20 in Cluster 2 (five from the eastern Mediterranean, one from the central Mediterranean and three from the western Europe subclades). Other alternative *K* groups did not increase the number of clusters in DC2 and showed higher admixture in the DC3 subclades (Supplementary Data Fig. S4). In all cases, sample R32 was always resolved with ~20 % admixture with the main genetic cluster of DC3.

Based on our phylogenomic and genetic structure analyses, we performed divergence time analysis using treePL and BEAST (Supplementary Data Fig. S5) using one representative sample of each defined clade and genetic group: D. orientalis, DC1, DC2 and DC3. Both approaches reconstructed an early Oligocene origin for the crown node of the Tamus and Borderea clades (BEAST 28.5 MY and treePL 28.2 MY), and a late Miocene split for the two species of the Borderea clade (BEAST 8.1 MY and treePL 10.6 MY). The split of D. orientalis from D. communis was inferred to have occurred during the early Miocene (BEAST 18.2 MY and treePL 20.6 MY), and the Macaronesian clade (DC1) likely diverged from the Mediterranean lineage of D. communis during the mid-Miocene (BEAST 13.5 MY and treePL 16.0 MY). The most recent split between clades DC2 and DC3 was estimated to have taken place during the late Miocene (BEAST 5.6 MY and treePL 6.6 MY).

The mean and median values of allelic ratios were >2 in all cases for *D. orientalis* and clade DC1, and only ten samples showed allelic ratio values <2: eight samples from clade DC2 and two samples from the eastern Mediterranean subclade of DC3 (Table 1). The lowest incidence of estimated polyploidy based on allelic ratio estimates was found in DC2, with 50 % of the samples classified as diploids (Table 1).

Current and past overlaps in species distribution ranges between the Tamus lineages

An ENM analysis was performed for each of the four lineages in the Tamus clade (Fig. 3) to explore whether differences exist in (former) distribution between the four clades

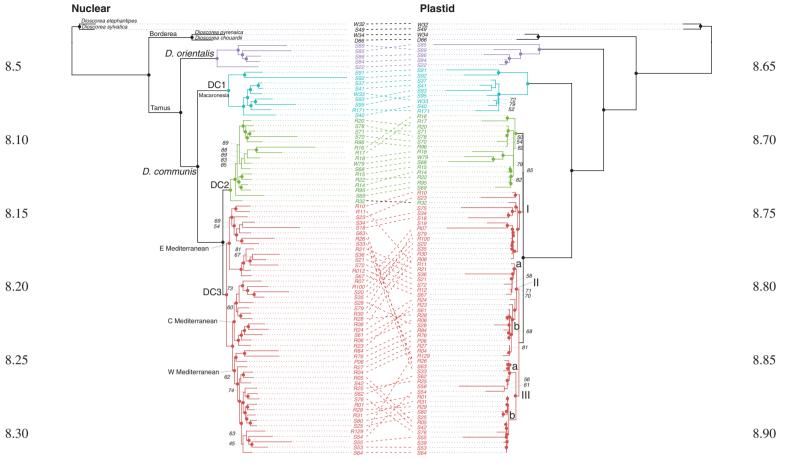

Fig. 1. Phylogenomic trees reconstructed using the concatenated and partitioned nuclear (left) and plastid (right) data obtained using Hyb-Seq for 76 samples of the Tamus clade of Dioscorea. Samples included are representative of its distribution range across the Mediterranean region. Filled circles represent branches with support values >90 % while lower values are shown on branches. Colours represent the main clades found in the nuclear tree (see Results section) (D. orientalis violet, DC1 blue, DC2 green, DC3 red), and roman numbers identify the subclades in D. communis in the plastid tree (I, II and III; subclades within each clade are indicated with lower-case letter a or b). Dashed lines connect the same samples in the nuclear and plastid trees.

identified within the Tamus clade of Dioscorea. Predicted distribution models were estimated using available occurrence data points (DC1, 27; DC2, 26; DC3, 218; D. orientalis, 17) and selected bioclimatic variables (DC1, bio16, bio9, bio15, bio3 and bio8; DC2, bio16, bio14, bio6, bio15, bio3 and bio8; DC3, bio4, bio8, bio16, bio15 and bio9; D. orientalis, bio16, bio14, bio6, bio15, bio3 and bio8; in order of importance), and showed high values of area under the curve (DC1, 0.9989 ± 0.0003 ; DC2, 0.980 ± 0.005 ; DC3, 0.937 ± 0.002 ; D. orientalis, 0.9994 ± 0.0001) and a 10 % threshold was applied (DC1, 0.24; DC2, 0.29; DC3, 0.20; D. orientalis, 0.50 probability).

The group formed by DC3 samples had its highest distribution probability in several Mediterranean areas, central and southern Europe (including England and Belgium to the Crimea), north-western Africa and western Asia (Turkey, Syria, Caucasus, Caspian shores). The most optimal distribution for DC2 was in the eastern Mediterranean, specifically in the eastern Aegean islands and the Mediterranean coastal zone of Turkey, Lebanon and Israel. The distribution model of the last group overlapped with the distribution range inferred for D. orientalis, which also presented its optimum in the eastern Mediterranean area, along the coasts of Lebanon, Syria, Palestine and Israel. The highest probabilities of potential distribution ranges for the DC1 group are restricted to the humid areas of the western Canary Islands (Fig. 3), with Madeira and western Morocco showing a lower probability of occurrence. Overlap was observed between DC2, DC3 and D. orientalis in the eastern Mediterranean region, and between DC1 and DC3 in the Canary Islands.

The highest niche breadth obtained corresponded to the clade with the largest modelled distribution projection (i.e. 0.875 for the DC3 clade), followed by DC2 (0.731), D. orientalis (0.516) and DC1 (0.499). We calculated Schoener's D and Hellinger's I indexes as metrics of niche overlap between pairs of distribution models. The highest overlaps between current niches were found between the DC3 clade with DC1 (D = 0.52, I = 0.64) and DC2 (D = 0.48, I = 0.67), whereas D. orientalis showed lower overlap values with DC2 (D = 0.32, I = 0.60) and DC3 (D = 0.36, I = 0.48). Although niche overlap between the DC2 and D. orientalis clades showed the lowest values, a PCA using the raw bioclimatic data obtained from the studied samples did not differentiate between them (Fig. 4); a better separation was, however, found between DC3 and DC1. These results are

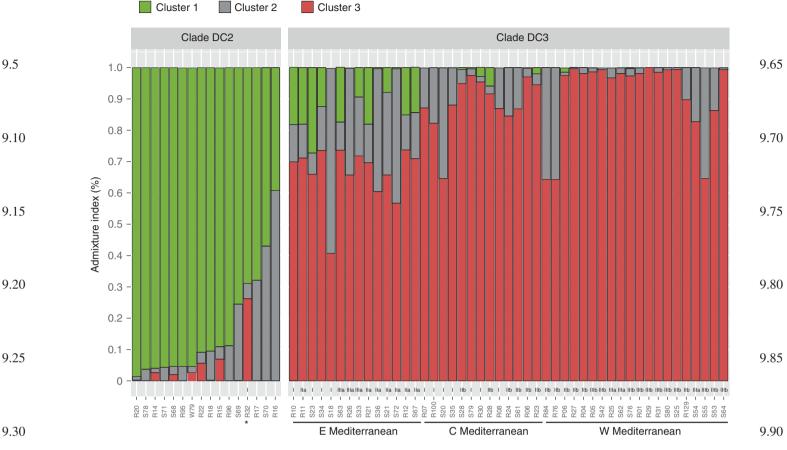

Fig. 2. Admixture proportions for K = 3 genetic groups obtained from genetic structure analysis of nuclear data of Mediterranean D. communis samples through ten replicates in Structure (see text for details). Each sample is shown by a vertical bar partitioned according to its membership in one of the K clusters, represented in red, green and blue. The samples follow the same order as in the nuclear phylogenetic tree (Fig. 1) and are organized by clades (DC2 and DC3). The plastid clades (I, II and III; Fig. 1) are labelled next to the sample codes. An asterisk (*) is used to represent the only sample of D. communis (R32) that was resolved as part of clade DC1 based on nuclear data, and in a different clade with plastid data (Fig. 1).

supported by observed differences between the four clades for each of the bioclimatic variables (Supplementary Data Fig. S6).

Hindcast species distribution models projected to the past (Supplementary Data Fig. S7) support a long-term presence of D. orientalis and DC2 clades in the eastern Mediterranean region, and a prevalence of the DC3 clade in the western Mediterranean since the LIG (~120 000-140 000 years BP). The overlap between current and MH (~6000 years ago) distribution models was high for DC2 (0.907), D. orientalis (0.798) and DC3 (0.859), slightly lower between the MH and the LGM (~22 000 years ago) for DC2 (0.835), D. orientalis (0.564) and DC3 (0.719), and moderately to drastically lower between the LGM and the LIG for DC2 (0.216), D. orientalis (0.419) and DC3 (0.558).

Identification of morphological traits defining taxa based on lineage divergences in the Tamus clade

We explored whether differences may exist between the four clades identified in the Tamus clade of Dioscorea in macro- and micromorphological characteristics (Fig. 5). Only three traits (male flower pedicel, female inflorescence length and leaf coverage) were found to have a normal

distribution (Supplementary Data Table S3). An assumption of homoscedasticity was corroborated using a Levene test for these variables. In the vegetative traits analysed 9.100 (Supplementary Data Table S2), we found significant differences between clades in leaf area, including leaf length, leaf width, leaf perimeter and petiole, while leaf coverage and the main nerve length and leaf length ratio did not show significant differences between groups (Supplementary Data 9.105 Table S3). Regarding reproductive traits (Supplementary Data Table S2), we found significant differences in male individuals for the total length of the inflorescence, the length of pedicels and the number of fascicles, but the number of flowers did not show significant differences (Supplementary Data Table S3B). The following morphological traits showed 9.110 Pearson correlations >0.7 (Supplementary Data Fig. S8): leaf length, leaf width, leaf area, leaf perimeter, petiole, leaf coverage, main nerve length, leaf length ratio, inflorescence length and number of flowers. We therefore selected leaf 9.115 area, leaf coverage and male inflorescence length as potential diagnostic variables. Post hoc analyses were performed (Supplementary Data Table S3), and we used these statistical differences to describe the morphological variability of each genetic group in Table 2.

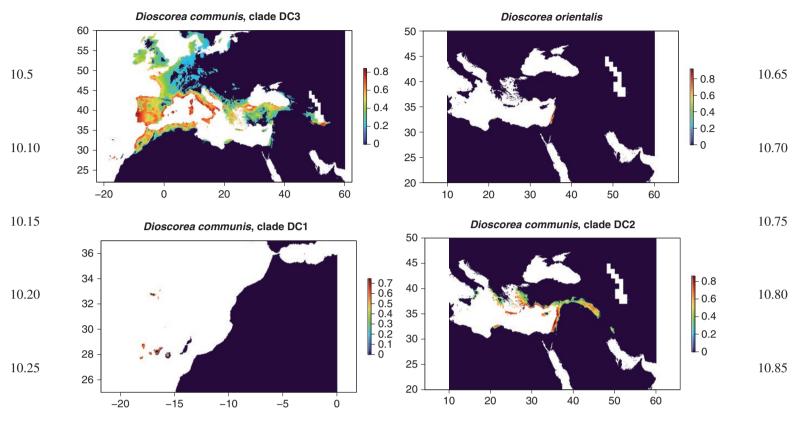

Fig. 3. Environmental niche models constructed using a current climate envelope and occurrence data for the samples of the Tamus clade of Dioscorea analysed AQ16 10.30 in this study. The ENMs were estimated for each of the four lineages identified in the Tamus clade with background maps adjusted to reflect their estimated po-10.90 tential distributions: DC3 clade of D. communis; DC2 clade of D. communis; the Macaronesian DC1 lineage of D. communis; and D. orientalis. A 10 % threshold cropping was applied for each distribution range model (see Results section). The scale bars represent the prediction of probability of occurrence.

10.35 Morphological differences were found between the four clades and served as diagnostic characters in an identification key to distinguish the four distinct species (see Identification key below); these morphological features matched the genetic and niche data of these taxa. Our multidisciplinary approach 10.40 combining genetic, spatial and morphometric data has delimited four taxa at species level, three species in the previously recognized D. communis sensu lato, namely D. communis sensu stricto, D. edulis and D. cretica, plus D. orientalis.

10.45 Identification key for Dioscorea communis, D. cretica, D. edulis and D. orientalis

- 1a. Flowers sessile, solitary; leaf pedicel up to 1.6 cm, shorter than leaf D. orientalis
- 1b. Flowers pedicellate in fascicles (2-4 flowers each); leaf 10.50 pedicel leaf pedicel up to 10.1 cm, usually longer than leaf
 - 2a. Leaves cordate-sagittate; perigonium violet; Macaronesia D. edulis
- 2b. Leaves cordate-trilobed; perigonium whitish-greenish; not 10.55 in Macaronesia 3
 - 3a. Leaves cordate (rarely trilobed in Balearic Islands); flowers turbinate infundibuliform D. communis
 - 3b. Leaves trilobed; flowers urceolate D. cretica

10.59 10.60 Taxonomic treatment and descriptions

1. Dioscorea orientalis (Thiébaut) Caddick & Wilkin Basionym= Tamus orientalis Thiébaut., Bull. Soc. Bot. France 81: 119.

 Holotype: Lebanon, Between Batroun and Saïda, January 1933, Thiébaut s.n. (P00301666).

Perennial herb, glabrous. Stems simple or little branched. Leaves ovate, acuminate, cordate at the base of up to 56×48 mm, petiole with glandular base. Flowers sessile, in axillary spikes, hanging 1–23 (male), 1–4 (female) flowers. Whitish-purple (i.e. including a range of shades of purple) perigonium; six lobes, recurved ovals. Six stamens, three stigmas and six naked filaments (female). Bracteoles 1–2 widely ovate, with final peak, adpressed perigonium, with a hull in the outer surface. Fleshy fruit, oblong, $7-11 \times 6-10$ mm, red at maturity. Pollen grains (Supplementary Data Fig. S9) with two apertures with longer axis up to 40 µm and shorter axis up to 30 µm. Perforated with 1.9 perforations per micrometre and perforation size up to 0.85 μ m, with spines. Eastern Mediterranean region. 2n =unknown.

2. Dioscorea edulis (Lowe) Campos, Wilkin & Viruel, comb. nov. (= Clade DC1) = Basionym: Tamus edulis Lowe, Trans. Cambridge Philos. Soc. 4: 1. 1833.

- Type: Portugal, Madeira, Pta Moniz, 7 May 1828, Herb. 11.50 Lowe 504 (K; K000099334!, K001081657!).

Heterotypic synonyms:

11.55

11.59

- = Tamus canariensis Willd. ex Kunth, Enum. Pl. 5: 455. 1850, nom. illeg. pro syn. Type: Spain, Canary Islands, Herbarium Willdenow no. 18374 (B-W).
- = Tamus parviflora Kunth, Enum. Pl. 5: 454. 1850. Holotype: Spain, Canary Islands, Teneriffa, ex Museo Paris, 1821 (B 10 0160963!), male plant.
- Perennial herb, glabrous. Leaves varying from cordiform to sagittate, petiole 1.60–3.88 cm, leaves up to 125×110 mm,

slightly wavy, coarse, chartaceous and secondary veins visible, 11.110 but not prominent. Male inflorescence compound is arranged in fascicles of three or four flowers, compound inflorescence up to 12 cm in length and bearing up to 65 flowers in total. Female flowers composed of six violaceous tepals with erect filaments. Fruit a globose berry, $6-12 \times 1-8$ mm, reddish-orange. Pollen grains (Supplementary Data Fig. S9) with two apertures with longer axis up to 36 µm and shorter axis up to 18 µm. Perforated with 3.9 perforations per micrometre and perforation size up to 0.37 µm, without spines. Macaronesia (Madeira, Gran Canaria, Tenerife, Gomera, Hierro, La Palma). 2n = 36, 48.

3. Dioscorea cretica (L.) Campos, Wilkin & Viruel, comb. nov. (= Clade DC2) Basionym: Tamus cretica L., Sp. Pl., 1028. 1753.

= *Tamus communis* L. subsp. *cretica* (L.) Kit Tan, Notes Roy. Bot. Gard. Edinburgh 41(1): 47. 1983.

– Neotype (designated by Kit Tan in Davis, 1984, as isotype, corrected by Jarvis, 2007): 'Habitat in Creta', Herb. Tournefort no. 283 (P-00665856!).

Perennial herb, glabrous. Leaves deeply trilobate, or apex or basal lobes elongated from a cordate leaf, up to 70×70 mm,

12.59

12.60

with 3–9 prominent main nerves and secondary reticulated nerves not visible. Male inflorescence branched, to 25 cm long with up to 50 flowers in total, short female inflorescence up to 7 cm with 1–6 urceolate, greenish-yellow flowers. Fruit a globose berry, 7–11 × 6–10 mm, reddish-orange. Pollen grains (Supplementary Data Fig. S9) with two apertures with longer axis up to 36 μ m and shorter axis up to 29 μ m. Perforated with 0.5 perforations per micrometre and perforation size up to 1.2 μ m, without spines. Eastern Mediterranean. 2n = unknown.

DISCUSSION

Species discovery based on integrative approaches

The biological species concept (Mayr, 1942) defines a species 14.5 as a group of populations reproductively isolated from others. This concept is difficult to apply to species delimitation in flowering plants due to the high incidence of hybridization and introgression (Mitchell et al., 2019). Although plant taxonomy has relied on morphological traits to differentiate and discover 14 10 new taxa for centuries using a typological species concept (Haider, 2018), biological processes such as hybridization can obscure the morphological attributes used to differentiate species. Combined morphological and molecular approaches have been used to identify cryptic species in angiosperms (Maguilla 14.15 and Escudero, 2016). Alternative species concepts have been proposed in plants to accommodate a broad spectrum of approaches, such as cytology, phytochemistry, anatomy, embryology or phylogenetics (De Queiroz, 2007; Aldhebiani, 2018). These are method-based concepts, such as the evolutionary 14.20 species concept using phylogenetic inference, or the ecological species concept based on niche differentiation.

The use of infraspecific ranks in plants has been discussed widely in the literature (e.g. Hamilton and Reichard 1992; Vogel Ely et al., 2018; Huang et al., 2020). Subspecies in plants have been defined as non-overlapping geographic populations with morphological differences (Patten and Remsen, 2017) or, considering additional sources, defined as taxonomic units supported by genetic markers, statistically distinguishable based on morphology and with geographic, ecological and/or reproductive isolation (Hardion et al., 2017).

Here, we have used an integrative approach combining morphological, phylogenetic and ecological niche data to decipher species delimitation in the Tamus clade of Dioscorea and uncovered the existence of introgression in some individuals (Fig. 2) that could at least partly explain the overlap in some of the morphological characteristics between taxa. The discovery of cryptic species in this group shapes our current understanding of it, specifically for what has been to date accepted as D. communis (Caddick et al., 2002). Based on our results, we propose the maintenance of D. orientalis as a species and divide D. communis sensu lato into three distinct species: D. communis s.s., D. edulis and D. cretica (see Results section; Fig. 6). The three taxonomic units identified in our study within D. communis s.l. are supported by morphological, cytological, ecological and evolutionary differentiation, and we therefore propose maintaining the species rank for them.

The emergence of HTS methodologies has allowed the detection of cryptic species (Carstens and Satler, 2013), the resolution of complex phylogenetic trees (Bogarín *et al.*, 2018; Frajman *et al.*, 2019; Hassemer *et al.*, 2019; Yang *et al.*, 2019) and the reconstruction of evolutionary patterns in extinct species (Moreno-Aguilar *et al.*, 2020). Thus, HTS methods provide new sources of useful data to clarify phylogenetic enigmas that classical molecular methods could not decipher (e.g. Urtubey *et al.*, 2018). Among HTS methods, target capture is currently being used in a broad number of plant systematics and evolutionary studies due to its versatility in successfully sequencing hundreds of loci from highly degraded DNA samples (Brewer *et al.*, 2019; Viruel *et al.*, 2019). Herbarium samples constitute a

valuable and vast source of information for morphological and niche modelling approaches, and recently proved to be equally important for phylogenetic studies based on DNA sequence data obtained using HTS methods (Brewer et al., 2019; Viruel et al., 2019). In our study, we used herbarium material, with the oldest specimen sequenced collected in 1788, and a custom bait capture kit targeting 260 low-copy nuclear genes (Soto Gomez et al., 2019), to reveal the evolutionary patterns and relationships between taxa belonging to the Tamus clade of *Dioscorea* (Fig. 1). By sequencing 76 samples of the Tamus clade, the phylogenomic and genetic clustering approaches revealed extensive infraspecific variability in D. communis s.l., clearly dividing it into three genetic groups, each showing a distinct geographic distribution across the Mediterranean and western Europe (Fig. 6). Two of these genetic groups are congruent with the previously recognized Tamus edulis and T. cretica, which were recently placed within the large morphological variability and wide distribution of D. communis s.l. Application of HTS methodologies to herbarium material allowed us to recognize the species rank of these genetic groups and to support the split of D. communis s.l. into D. edulis, D. cretica and D. communis, and to maintain D. orientalis as a species.

Whole-genome duplication events (i.e. polyploidy) have been commonly reported across flowering plants and have been correlated with diversification of gene functions and new genetic architecture, which could be linked to adaptative traits (Wendel et al., 2018). Increased speciation events have been observed in some angiosperm lineages reported to have a high incidence of whole-genome duplication events (Wood et al., 2009; Zhan et al., 2016). Polyploidy is a common phenomenon, and has been frequently reported in several Dioscorea species (Viruel et al., 2008), although defining the ploidy of the Tamus and Borderea clades has been challenging. The two Dioscorea species belonging to the Borderea clade, D. chouardii and D. pyrenaica, have chromosome counts of 2n = 24. Based on the discovery of allotetraploidy using microsatellite markers (Segarra-Moragues et al., 2003), it was proposed that the chromosome base number for the Borderea clade was x = 6(see also Viruel et al., 2008). Extrapolating this find to the sister Tamus clade, the known chromosome counts reported for D. communis s.s. of 2n = 36 and 48 (Al-Shehbaz and Schubert, 1989; Viruel et al., 2019) would therefore represent hexaploid and octoploid forms, respectively. Similarly, the Macaronesian D. edulis, with 2n = 96, would be 16-ploid assuming a base chromosome number of x = 6. Using flow cytometry to estimate ploidy in D. communis s.s., multiple ploidies were observed (1C values ranging from 0.41 to 1.36 pg; Viruel et al., 2019). The chromosome number and genome size of *D. orientalis* and D. cretica remain unknown, but allelic ratios estimated for each SNP per sample using HTS data can be used as a proxy to distinguish between diploid and polyploid forms when multiple ploidies are expected in a group of plants (Viruel et al., 2019). Median and mean values of allelic ratios based on the number of reads supporting each SNP were recently proposed to classify Dioscorea samples as diploid forms when the allelic ratio is <2, and polyploids when the ratio is >2 (Viruel et al., 2019). For example, all samples of *D. edulis* had mean and median allelic ratios >2 (Table 1), confirming the polyploid nature of this species based on chromosome data. In all cases, the D. orientalis samples studied here showed allelic ratios >2 and

would therefore be estimated to be a polyploid species (Table 1). For D. communis s.s., all samples were estimated to be polyploids except for two samples of clade DC3 from the eastern Mediterranean with mean and median allelic ratio values <2 16.5 (samples S67 and R12; Table 1). Samples estimated to be diploid based on allelic ratios were also observed in D. cretica, with half of the samples (eight) having average and median allelic ratios <2 (Table 1). The incidence of diploid forms, as estimated using allelic ratio values, in the eastern Mediterranean 16.10 will require further investigation applying cytological and flow cytometry methodologies.

Evolutionary patterns of the Tamus clade of *Dioscorea* in the 16.15 Mediterranean

Overall evolutionary patterns of Dioscorea lineages have been thoroughly studied using plastid markers (e.g. Wilkin et al., 2005; Hsu et al., 2013; Maurin et al., 2016; Viruel et al., 2016) and low-copy nuclear genes (e.g. Viruel et al., 2018; Soto Gomez et al., 2019). Previous studies determined that yams have diverged and expanded since the Late Cretaceous, probably from Laurasia, and that a split of the African-Mediterranean lineage, which includes the Tamus clade, likely occurred in the Oligocene, following a westward migration ~33 MY (Viruel et al., 2016). Fossil records indicate that Dioscorea ancestors persisted in Europe during the Oligocene (Andreanzky, 1959). Based on data from four plastid markers, the split between the two Mediterranean clades, Borderea and Tamus, was estimated to have occurred during the late Oligocene (~25.7 MY) (Viruel et al., 2016), a similar divergence time to the one we obtained with our analyses based on 260 nuclear genes, which indicate that this divergence took place in the early Oligocene (28.2–28.4 MY); Supplementary Data Fig. S5). Two narrowly endemic species of the Borderea clade survived in refugia in the Pyrenean mountains: D. chouardii, a critically endangered species with only one known locality (Goñi Martínez and Otano, 2011), and D. pyrenaica, with a slightly wider distribution in the central Pyrenees and Pre-Pyrenees (Segarra and Catalán, 2005; Catalan et al., 2006; Segarra-Moragues and Catalan, 2008; García et al., 2012). A previous study (Viruel et al., 2016) estimated a split between these two species during the early Pliocene (~4.3 MY), whereas our results indicated that this divergence likely occurred during the late Miocene (8.1-10.6 MY). The differences observed in divergence times for the Tamus

clade in comparison with previous studies are a consequence of the newly recognized species (D. cretica). In Viruel et al. (2016), the crown node of the Tamus clade was estimated to be 15.3 MY [D. edulis (D. communis, D. orientalis)], and the subsequent split between D. orientalis and D. communis at 10.4 MY. However, the samples of D. orientalis included in Viruel et al. (2016) have now been reidentified as D. cretica, and thus the older age estimates herein for the crown node of the Tamus clade (20.6-18.2 MY) demonstrate an early split of D. orientalis in the eastern Mediterranean, followed by a split of D. edulis ~16.0 13.5 MY, and the divergence of D. communis s.s. and D. cretica ~6.6-5.6 MY. Given the findings presented here, with a sampling representative of the whole distribution range of the Tamus clade across the circum-Mediterranean region, we conclude that the divergence times estimated here are more robust and taxonomically more representative, which allowed us to reassess the species delimitation in this group.

The Mediterranean region is considered one of the major biodiversity hotspots of the world (Médail and Quézel, 1997). Fossil records and evolutionary studies have confirmed that the ancestors of several plant lineages were part of a tropical flora that occupied the Mediterranean region during the Miocene and early Pliocene (Suc et al., 2018). The drastic subsequent climatic changes that came during the Pliocene (3.5–2.4 MY), with a significant drop in temperature and a marked seasonality in thermal and rainfall regimes, impacted the diversification patterns of plant lineages and resulted in narrow endemics in the margins of the distribution range of their sister species (e.g. Ceratonia oreothauma; Viruel et al., 2020). The diversification of species in the Tamus clade likely occurred during the Miocene, when subtropical climatic conditions were present across the Mediterranean (Suc et al., 2018). The most recent common ancestor of all Tamus clade taxa likely diversified during the early Miocene (20.6–18.2 MY), when the lineages that gave rise to the current D. orientalis and the clade comprising the three lineages of *D. communis s.l.* likely split. This was followed by a subsequent split of the Macaronesian D. edulis that would have taken place in the mid-Miocene (16.0-13.5 MY), after the formation of some of the Canary Islands, which has been estimated to have started around 23 MY (Sanmartín et al., 2008; Florencio et al., 2021). The most recent split between D. communis s.s. and D. cretica is estimated to have occurred during the Messinian (Miocene, 6.6–5.6 MY). During this period, the significant and rapid lowering of the sea level of the Mediterranean also resulted in new terrestrial biogeographic connections allowed by the formation of land bridges.

Several phylogeographic studies have attempted to explain the biodiversity patterns and processes that shaped the Mediterranean region and its development into one of the world's biodiversity hotspots (e.g. Nieto Feliner, 2014; Thompson, 2021). Two main areas of high plant endemism were identified in the western (Iberian Peninsula and Morocco) and eastern Mediterranean (including Turkey and Greece) (Médail and Quézel, 1997). In both these areas, Quaternary glaciations likely played a major role in shaping the distribution of species and left a footprint in the genetic structure of many Mediterranean species, particularly in refugia (Médail and Diadema, 2009). Western and eastern genetic groups have been identified in the phylogeographic patterns of several Mediterranean plants, leading to disjunct distributions in some cases, such as in Microcnemum (Amaranthaceae) and Mandragora (Solanaceae) (Kadereit and Yaprak, 2008; Volis et al., 2018), or by differentiating morphotypes that later hybridized in intermediate zones (e.g. Quercus ilex; Lumaret et al., 2002). The strong geographic influence in the genetic structuring of *D. communis* across the Mediterranean may have also been slightly influenced by bird dispersal. Bird dispersals have contributed to shaping the postglacial recolonization of the Mediterranean, such as seen in Frangula alnus (Hampe et al., 2003). The birds that consume berries produced by species of the Tamus clade, mainly blackbirds (Turdus merula), robins (*Erithacus rubecula*) and blackcaps (*Sylvia communis*) (Chiscano, 1983; Herrera, 1984), are predominantly sedentary

birds or have modern migratory routes that do not strictly coincide with the past and current distribution patterns estimated in this study (Adriaensen, 1988; Burfield and Van Bommel, 2004). It would thus be useful to analyse the patterns of genetic structure at the population level of D. communis s.s. in more detail, and the introgression between D. communis and D. cretica, in connection with the possible magnitude of ornithochory, which has never been studied in detail to our knowledge.

Changes in ploidy, morphological differences and introgression between the central Mediterranean and western European populations have been shown to have occurred between the D. communis s.s. and D. cretica lineages (Figs 2 and 5). The central-eastern Mediterranean area constitutes the contact region between these two species and is congruent with the introgression patterns found in our study (Fig. 2). Five out of 16 samples studied of D. cretica exhibited an admixture index <20 % with D. communis s.s., and all individuals of D. communis belonging to the eastern clade of D. communis s.s. showed an admixture index <20 % with D. cretica (Fig. 2). However, only four individuals from the central Mediterranean and western European subclades of D. communis were detected as introgressing with a sister species, and one sample of D. cretica was placed in a clade of D. communis s.s. in the phylogenetic tree based on plastid data (R32, Fig. 1). These results are congruent with their potential distribution in disjunct refugia followed by secondary contact through recolonization, and by maintaining some capacity for interspecific gene flow between closely related species (Viruel et al., 2021). The topological incongruencies found between the nuclear and plastid phylogenetic trees, indicative of plastid capture events (Fig. 1), are congruent with these hypothesized introgression patterns: plastid clades I and II are found in the central and eastern Mediterranean lineages without a clear geographic separation (Fig. 6), whereas clade III is uniquely found in the western part of the Mediterranean, where lower introgression events have been inferred.

The identification of new plant species usually requires a broad understanding of taxon boundaries applying multidisciplinary methodologies. Our study exemplifies the complexity of identifying new species by integrating different types of data: target capture sequencing data from herbarium specimens to reveal phylogenomic patterns and introgression between clades, differences in allelic ratios to estimate ploidy, spatial analysis estimating current and past distribution ranges and niche overlaps, and macro- and micromorphometric comparisons. By integrating all these results, we have newly corroborated the existence of four species in the Mediterranean Tamus clade of Dioscorea, maintaining D. orientalis as a distinct species, and demonstrating that D. edulis and D. cretica are species discrete from the synonymy of the morphologically variable D. communis.

SUPPLEMENTARY DATA

Supplementary data are available online at https://academic. oup.com/aob and consist of the following. Table S1: Dioscorea samples used with the name of the species, collector's name

and collection number, date of collection and location of the individuals. Table S2: traits used for morphometric analyses of the Tamus clade of *Dioscorea* samples. Table S3: results of the Lilliefors test, Levene test and the subsequent ANOVA or Kruskal-Wallis test for the selected variables analysed in 17.65 the Tamus clade of *Dioscorea* samples. Figure S1: dendrograms constructed from correlation values between bioclimatic variables for the samples belonging to the D. communis and D. orientalis clades. Figure S2: phylogenomic trees reconstructed for 76 samples of the Tamus clade of Dioscorea using 17.70 ASTRAL-III, SVDquartets and the haplotype network. Figure S3: results obtained in Structure Harvester based on genetic structure analysis of D. communis nuclear data though 10 replicates of Structure for each K. Figure S4: genetic structure analysis of nuclear SNP data of the studied Mediterranean D. 17.75 communis samples with Structure. Figure S5: divergence time estimations and chronograms of the Tamus clade of Dioscorea and outgroup based on nuclear sequence data. Figure S6: boxplots representing the differences between the four main clades. Figure S7: past projections of the ENMs constructed 17.80 for the four Tamus clades of Dioscorea. Figure S8. Pairwise Pearson correlation matrix calculated between the morphological variables measured to distinguish between Tamus clade taxa. Figure S9: scanning electron microscope images of the pollen grains of D. communis DC3 clade, D. cretica, D. edulis 17.85 and D. orientalis.

FUNDING

This work was supported by a Marie Skłodowska-Curie Individual Fellowship (704464 – YAMNOMICS – MSCA-IF-EF-ST) and the RBG Kew-funded pilot study to Juan Viruel; and Erasmus+ Programme for Miguel Campos. Emma Kelley received funding from the Muriel Kohn Pokross '34 Travel/ Internship Fund, Smith College, Massachusetts. Pilar Catalán was supported by a European Social Fund and Spanish Aragón Government Bioflora grant.

ACKNOWLEDGEMENTS

We are thankful to the herbaria of Kew (K) and Seville (SEV) for providing access to their collections for this study and to the colleagues who collected samples in the field. 17.105
