ABSTRACT: The mononuclear square-planar $\text{Rh}\{\kappa^2\text{-X}_2\text{N}(\text{Xpy})\}(\eta^2\text{-coe})(\text{IPr})$ ($\text{X} = \text{O}, \text{NH}, \text{NMe}, \text{S}$) complexes have been synthesized from the dinuclear precursor $[\text{Rh}(\mu\text{-Cl})(\text{IPr})(\eta^2\text{-coe})]_2$ and the corresponding 2-heteroatom-pyridinate salts. The Rh–NHC–pyridinato derivatives are highly efficient catalysts for *gem*-specific alkyne dimerization. Particularly, the chelating N,O-pyridonato complex displays turnover frequency levels of up to $17\,000\text{ h}^{-1}$ at room temperature. Mechanistic investigations and density functional theory calculations suggest a pyridonato-based metal–ligand cooperative proton transfer as responsible for the enhancement of catalytic activity. The initial deprotonation of a Rh– π -alkyne complex by the oxo-functionality of a κ^1 -N-pyridonato moiety has been established to be the rate-limiting step, whereas the preferential protonation of the terminal position of a π -coordinated alkyne accounts for the exclusive observation of head-to-tail enynes. The catalytic cycle is closed by a very fast alkenyl–alkynyl reductive elimination.

KEYWORDS: metal–ligand cooperation, ligand assisted proton shuttle, alkyne dimerization, N-heterocyclic carbene, DFT calculations, hemilability

INTRODUCTION

Organometallic catalysis is nowadays at the central core of the preparation of elaborated organic structures owing to a continuous design of new metal–ligand architectures.¹ Undoubtedly, the high levels of catalytic efficiency have been achieved due to a precise control of reactivity through detailed determination of mechanistic issues. In this context, the concept of metal–ligand cooperation (MLC) has emerged as an essential piece in organometallic-mediated bond cleavage and formation, particularly for dihydrogen activation and related reactions.² The synergic effect arising from MLC generally triggers an enhancement of catalytic activity and provides better control of selectivity. A particular case of MLC arises when a ligand acts as a carrier for a proton from one substrate to the other for which the term ligand assisted proton shuttle (LAPS) has been coined (Scheme 1).³ Besides its competence in the originally proposed alkyne–vinylidene tautomerization,⁴ LAPS pathways have been proposed in catalytic intramolecular cyclizations⁵ and stoichiometric intermolecular reactions,⁶ but scarcely applied to catalytic intermolecular transformations.⁷

Alkyne dimerization is a practical and atom economical access to 1,3-enynes as key structural elements in a variety of biologically active molecules and functional organic materials.⁸ Efficient catalysts spread across the periodic table, from f-block,⁹ early¹⁰ or late transition metals,¹¹ to main group elements.¹² Moreover, earth-abundant transition metals of the

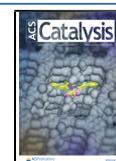

first row¹³ or organocatalysts¹⁴ have recently emerged. Due to the inherent rich chemistry of alkynes, the formation of head-to-tail (*gem*) or head-to-head (*E/Z*) enynes is commonly in competition with the formation of a myriad of oligomeric, polymeric, or cyclic organic structures. Therefore, despite the fact that remarkable advances in the selective preparation of *E*,^{11b,g,13b} *Z*,^{9c,10b,13c,e} or *gem*-enynes,^{13d,f,i,14a} further research effort is still desirable, particularly in mechanism elucidation.

Four general pathways have been proposed for transition-metal mediated alkyne dimerizations:¹¹ⁱ (i) external attack on the coordinated π -alkyne; (ii) oxidative addition of a terminal alkyne; (iii) nonoxidative base-mediated formation of metal-alkynyl species; and (iv) dimerization via a vinylidene intermediate. It has been rationalized that the nonoxidative route iii would be the preferred approach for the selective preparation of *gem*-enynes (Scheme 2).¹¹ⁱ Initial deprotonation of the alkyne leads to metal-alkynyl species. Noteworthy, an MLC effect has been claimed in the case of an internal base.^{11f,13d,f,g,i} Then, the pathway continues by an insertion of another alkyne into metal-alkynyl bond and subsequent

Catalyst Design

protonolysis by the conjugated acid of the initial base (MLC or not) or an alkyne itself. Although this pathway takes advantage of the benefits of MLC in deprotonation or protonolysis, the key insertion step, which determines the selectivity and is usually rate-limiting, remains excluded from the metal–ligand cooperative influence. An alternative approach can be envisaged in which metal and ligand would act in cooperation throughout the whole catalytic cycle. After the initial deprotonation of an alkyne molecule, the resulting protonated ligand could transfer the hydrogen atom to a second molecule of the alkyne in an oxidatively manner that yields a Rh^{III} -alkenyl-alkynyl species. Subsequent reductive elimination will close the catalytic cycle. An MLC effect is expected to result in lowering the key energetic barriers. Indeed, the selectivity determining step changes from a mainly sterically ligand-controlled carbometalation in iii to a Markovnikov-type electronically and sterically favored protonation on a coordinated alkyne, therefore enhancing specific *gem*-enyne formation.

Recent results from our laboratories have revealed that coordination of an *N*-heterocyclic carbene (NHC) ligand to rhodium complexes resulted in efficient alkyne dimerization catalysts.^{11i,15} Several chelate 1,3-bis-heteroatomic acidato (BHeta) ligands, such as carboxylato, thioacidato, or amidato, have demonstrated their utility as internal bases to selectively promote the formation of head-to-tail enynes. Now, along this line, we hypothesize that increasing the robustness of the chelate interaction should allow the anionic ligand to act not only as a base but also as an efficient proton shuttle. In this regard, pyridine-like moieties have previously been efficiently anchored to Rh -NHC platforms.¹⁶ Thus, 2-heteroatom-substituted pyridine ligands appear to be promising candidates to fulfill the requirements of a BHeta structure with tight chelate coordination.¹⁷ Particularly, 2-pyridonate moieties have been shown to act as versatile proton-responsive ligands¹⁸ which can behave as powerful internal bases¹⁹ as well as efficient proton shuttles.²⁰ Moreover, its proven hemilability²¹ would be key for the generation of vacant sites and the proton transfer process. Herein, we report on the preparation of Rh^{I} -

NHC-pyridinato derivatives and their application as catalysts for *gem*-specific alkyne dimerization. Experimental and theoretical studies have revealed a rhodium-pyridonato LAPS process as responsible for the enhancement of catalytic activity.

RESULTS AND DISCUSSION

Preparation of Rh-Pyridinato Catalysts. The dinuclear precursor $[\text{Rh}(\mu\text{-Cl})(\eta^2\text{-coe})(\text{IPr})_2]$ (**1**) {IPr = 1,3-bis(2,6-diisopropylphenyl)imidazolin-2-carbene; coe = cyclooctene} reacts with a THF solution of deprotonated 2-heteroatom-pyridine compounds to yield BHetA derivatives $\text{Rh}\{\kappa^2\text{-X,N}(\text{Xpy})\}(\eta^2\text{-coe})(\text{IPr})$ {py = $\text{C}_5\text{H}_4\text{N}$, X = O (**2**), NH (**3**), NMe (**4**), S (**5**)} (Scheme 3). The new complexes were obtained as yellow–orange solids with 55–72% yields. It is worth mentioning that complex **2** can be directly obtained by reaction of **1** with 2-pyridone in the absence of an external base, although in low yield and purity. Moreover, in contrast to related 8-quinoline derivatives,^{16a} no O–H oxidative addition to yield Rh^{III} -hydride species was observed. On the contrary, the reaction of **1** with the more acidic 2-mercapto-pyridine resulted in the formation of several Rh^{III} -hydride species, as reflected in the appearance of ^1H NMR highly shielded doublets. As far as we know, the coordination of the 2-heteroatom-pyridinato moiety into an Rh-NHC framework is unprecedented.^{22–25}

The solid-state structure of the pyridonato complex **2** was elucidated by X-ray diffraction analysis. An ORTEP view of the molecule with selected bond lengths and angles is displayed in Figure 1. A mononuclear structure with a rare chelate arrangement²² of the 2-pyridonato ligand is observed instead of the more typical μ -bridge dinuclear assembly.²³ The crystal structure exhibits a distorted square planar geometry at the metal center with the IPr in a *cis* arrangement with respect to coe [C(1)–Rh–ct 94.32(6)°], and the oxygen atom in a *trans* disposition to the latter [ct–Rh–O(44) 168.82(4)°]. The Rh–C(1) bond length [1.947(2) Å] is similar to those already reported for Rh^{I} -IPr complexes.¹⁶ The imidazoliny ring deviates from the typical perpendicular *out-of-plane* configuration [N(5)–C(1)–Rh–O(44) –68.0(2)°] and the calculated pitch (θ 10.1°) and yaw (ψ 1.5°) angles^{16c} indicate a distorted coordination with respect to the Rh–C(1) bond. As for the chelate ligand, it exhibits a reduced bite angle [O(44)–Rh–N(38) 62.85(7)°] and a relatively small pitch angle (θ 2.9°), bringing about a severely distorted $\kappa^2\text{-N,O}$ coordination mode.²² In addition, the O(44)–C(39)–N(38) angle [113.8(2)°] is smaller than that reported for the free 2-pyridone²⁶ (121.3°). Finally, the short C(39)–O(44) bond

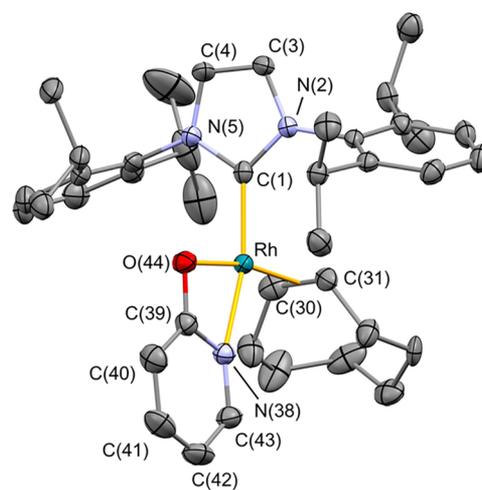

Figure 1. Solid-state crystal structure of **2**. For clarity, all hydrogen atoms are omitted. Selected bond lengths (Å) and angles (deg) are N(38)–Rh 2.1536(19), O(44)–Rh 2.1245(16), C(1)–Rh 1.947(2), Rh–ct 1.9655(2), C(30)–C(31) 1.393(4), C(39)–N(38) 1.366(3), C(39)–O(44) 1.297(3), C(1)–Rh–ct 94.32(6), ct–Rh–O(44) 168.82(4), ct–Rh–N(38) 106.02(5), C(1)–Rh–O(44) 96.78(8), C(1)–Rh–N(38) 159.59(8), O(44)–Rh–N(38) 62.85(7), O(44)–C(39)–N(38) 113.8(2), ct: centroid of C(30) and C(31).

length [1.297(3) Å] suggests a major contribution of the 2-pyridonato carbon–oxygen double bond tautomer.

The NMR spectra of **2** is in agreement with the solid-state structure; thus, we assume a related mononuclear square-planar configuration also for **3–5**. The $^{13}\text{C}\{^1\text{H}\}$ -APT NMR spectra corroborates the presence of IPr, coe, and 2-heteroatom-pyridyl ligands in **2–5** by the appearance of three carbon–rhodium coupled doublets, with a coupling constant $J_{\text{C-Rh}}$ of around 60, 15, and 3 Hz, respectively. The ^1H NMR spectra display the characteristic feature of a pyridinato moiety, namely, a deshielded doublet of doublets between δ 7.71 and 7.19 ppm, corresponding to the $\text{H}_{6\text{-py}}$ proton, in addition to shielded resonances around 6 ppm, ascribed to $\text{H}_{3\text{-py}}$ and $\text{H}_{5\text{-py}}$ atoms. Also of note is the observation of only one septuplet around 3 ppm for **2, 3**, and **5**, ascribed to the four CH-isopropyl protons of the wingtips of carbene. This fact is explained by the occurrence of a symmetry plane and a rotational process of the IPr ligand,²⁷ whose rate slows down as a function of temperature resulting in the observation of two broad signals at 203 K (See Figure S1 in the Supporting Information for **2**). The carbene rotation is hindered in **4** by the methyl group of the amino-pyridinato ligand. The presence of both nitrogenated ligands in **2–5** was

Mechanistic Investigation. In order to shed light on the operative mechanism for the Rh-NHC-pyridinato catalyzed alkyne dimerization, low temperature reactivity studies were made. Unfortunately, catalyst 2 dimerized phenylacetylene very fast, even at 213 K, thwarting the detection of catalytic intermediates. In view of this, reactivity studies were carried out with a less efficient catalyst or a less reactive alkyne (Scheme 5). Thus, the addition of phenylacetylene to the mercaptopyridine complex 5 at 233 K gave the π -phenylacetylene complex Rh{ κ^2 -S,N-(Spy)}(η^2 -HC≡CPh)(IPr) (6)¹¹ by alkyne-coe exchange, which can be proposed as the first step of the catalytic cycle. Warming the solution led to the smooth formation of the head-to-head and head-to-tail enynes, according to the selectivity observed in the catalytic experiments (entry 7, Table 1), and a mixture of unidentified complexes. In contrast, addition of the bulky trimethylphenylacetylene to 2 afforded Rh{ κ^2 -O,N-(Opy)}(η^2 -H₂C=C(Mes)-C≡C(Mes))(IPr) (7), that results from the η^2 -C=C coordination of the enyne reaction product formed by fast dimerization of the alkyne. This uncommon coordination mode for an enyne²⁹ is reflected in the appearance in the

Scheme 5. Reactivity of Pyridinato Complexes with Alkynes

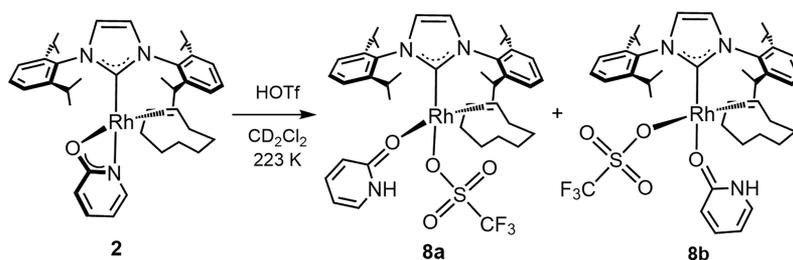

¹³C{¹H}-APT NMR spectrum of two doublets at δ 50.3 and 41.0 ppm with J_{C-Rh} around 18.8 Hz, corresponding to the coordinated olefin. Most likely, the presence of the bulky substituents in the proximity of the alkynyl moiety hinders the coordination of the triple bond.

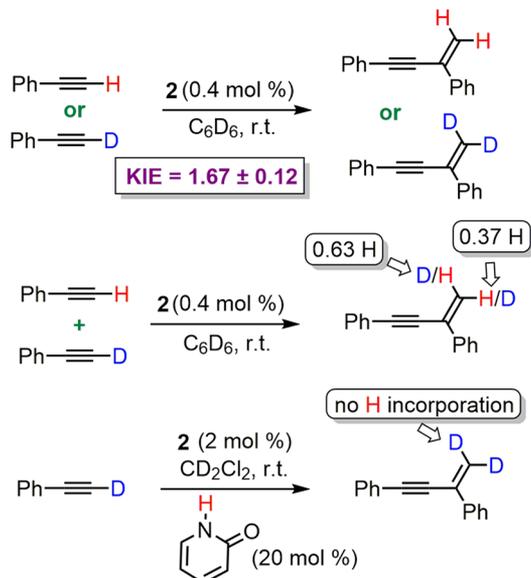

Based on previous investigations in our group,¹¹ the pyridinato ligand must play a role in the deprotonation of the rather acidic terminal proton of the alkyne. Thus, addition of triflic acid to a CD₂Cl₂ solution of 2 at 223 K resulted in the formation of Rh[κ^1 -O-{O=C(-CH=CH-CH=CH-)-NH}]{ κ^1 -O-(CF₃O₃S)}(η^2 -coe)(IPr) as a mixture of two isomers in a 1:1 ratio, tentatively assigned to 8a and 8b, where the nitrogen atom of the pyridonato ligand has been protonated (Scheme 6) (see Theoretical Calculations on the Mechanism section). The ¹H-¹⁵N HMQC NMR spectrum shows two NH cross-peaks at δ 174.0 and 170.3 which correlate with δ 11.73 and 10.97 ppm proton signals, respectively, thereby confirming the presence of pyridin-2(1H)-one ligands in both isomers. Moreover, the ¹⁹F NMR spectrum displays the typical broad signal of a coordinated triflate ligand.

Deuterium-labeling experiments using phenylacetylene-*d*₁ were performed with the aim of gaining information about the turnover limiting step (Scheme 7). First, the H/D kinetic isotopic effect (KIE) was measured by performing separate NMR experiments using 0.4 mol % of catalyst 2. A KIE of 1.67 ± 0.12 was found. This relatively small value suggests that a X-H cleavage or formation event is not likely involved in the turnover limiting step.³⁰ Further, a catalytic test with a mixture of natural and phenylacetylene-*d*₁ in a 1:1 ratio resulted in a different deuteration degree of the geminal positions of the enyne. The calculated H/D ratios show the overdeuteration of the vinyl proton *cis* to the phenyl group (0.37 vs 0.63 H). Taking into consideration a *syn* addition process and no preference between natural and deuterated alkyne as the acceptor partner, this result suggests that the cleavage of the C-H bond is 1.7 times faster than that of the C-D bond, which is in concordance with the calculated KIE. Moreover, the ability of the pyridonato ligand to act as an efficient shuttle was analyzed. The mixture resulting from a catalytic test with phenylacetylene-*d*₁ and 2 in the presence of natural pyridin-2-one resulted in the clean formation of *gem*-enyne-*d*₂. The lack of incorporation of protons from the heterocycle indicates that

Scheme 6. Protonation of 2 with Triflic Acid

Scheme 7. Deuterium Labeling Experiments

hydrogen transfer is faster than the metal-pyridone ligand coordination exchange.

Theoretical Calculations on the Mechanism. To further clarify the operating pathway leading to the observed *gem*-enyne selectivity, a detailed density functional theory (DFT) computational analysis on the dimerization of phenylacetylene promoted by the Rh-NHC-pyridinato complexes has been carried out. All plausible mechanistic pathways have been thoroughly examined (ΔG in kcal·mol⁻¹), excluding the external attack on coordinated π -alkyne and vinylidene-mediated dimerization pathways as these usually do not result in *gem*-selectivity.

The first step considered in this study is the preactivation of catalyst 2 by phenylacetylene-coe exchange via an associative mechanism. This exergonic process (-6.1 kcal·mol⁻¹) has an energetic barrier of 13.7 kcal·mol⁻¹ (see Figure S103 in the Supporting Information). The resulting complex Rh{ κ^2 -O,N-(Opy)}(η^2 -HC≡CPh)(IPr) (A) can be considered as the active species, and hence, it has been selected as the energetic reference for all DFT calculations in this section.

First, we have analyzed the pathway starting by oxidative addition of the alkyne to form a Rh^{III}-hydride-alkynyl intermediate.¹⁵ The energy profile of this cycle is shown in Figure 3. The initial step is the slippage of the η^2 -(C≡C)-alkyne bond in A rendering the η^2 -(C-H) agostic interaction in B. This process presents an energetic barrier characterized by TSAB of 19.9 kcal·mol⁻¹, and it is endergonic by 10.4 kcal·mol⁻¹. The formation of the σ -complex B is essential in the

cleavage of the C-H bond.^{10a,13b,d,f,h} From that point, the oxidative addition takes place by a negligible energy barrier, characterized by TSBC, leading to the Rh^{III}-hydride-alkynyl C, which presents a relative free energy of 8.3 kcal·mol⁻¹. The reaction continues by coordination of a second alkyne to the metal center and subsequent hydrometalation. The two possible orientations of the alkyne toward its insertion on the Rh-H bond are characterized by the transition states TSCDg (leading to the *gem* product) and TSCDt (leading to the *E* product), with free energies of 20.2 and 23.7 kcal·mol⁻¹, respectively. It should be noted that, although Dt is more stable than Dg, the reaction is under kinetic control and Dt is not accessible. The insertion of the alkyne into the Rh-C bond has been discarded based on previous studies on similar systems.^{11e,15a} The obtained alkynyl-alkenyl complexes D evolve to the final products via reductive elimination via TSDAg and TSDAt, showing energetic barriers of 7.4 and 12.4 kcal·mol⁻¹, respectively. This mechanistic proposal presents an overall activation energy of 20.2 kcal·mol⁻¹ for the *gem*-enyne, which is preferentially obtained due to the significantly higher barrier for the *E* product (23.7 kcal·mol⁻¹).

For the sake of comparison, a classical mechanism alternative to alkyne oxidative addition is a base-mediated nonoxidative pathway. In our case the pyridonate may play this role via a concerted metalation-deprotonation (CMD) process. The energetic profile is shown in Figure 4. The reaction starts by coordination of a second alkyne to A, allowed by the hemilabile behavior of the pyridonate ligand.²¹ As a result, a switch to a { κ^1 -N-(Opy)} coordination mode of this molecule is observed.³¹ This process is characterized by TSAE (energetic barrier of 14.2 kcal·mol⁻¹) leading to the intermediate E Rh{ κ^1 -N-(Opy)}(η^2 -HC≡CPh)₂(IPr), displaying a mutually *trans* disposition for the two π -alkyne molecules.³² Since the pyridonate ligand is now coordinated to the metal only by the nitrogen atom, free rotation about the Rh-N bond becomes possible thus enabling the easy approach of the basic oxo group to any terminal hydrogen of the η^2 -coordinated alkynes of E. Therefore, the subsequent CMD step is characterized by the TSEF transition state, which has an energetic barrier of 15.9 kcal·mol⁻¹, leading to the intermediate F Rh(-C≡CPh){ κ^1 -N-{HOpy}}(η^2 -HC≡CPh)(IPr). The possible deprotonation of the alkyne by the nitrogen atom of the pyridonate was also computed revealing a higher energetic barrier of 20.7 kcal·mol⁻¹ (TSEG see Figure S104 in the Supporting Information). However, the resulting pyridin-2-one intermediate G is almost isoenergetic to F, in accordance to the experimental observation that 8 forms after the protonation of 2 with triflic acid.

Once the Rh^I-alkynyl intermediate F is obtained, carbometalation is available via TSFHg (30.2 kcal·mol⁻¹) or TSFHp (26.5 kcal·mol⁻¹) depending on the orientation of the alkyne

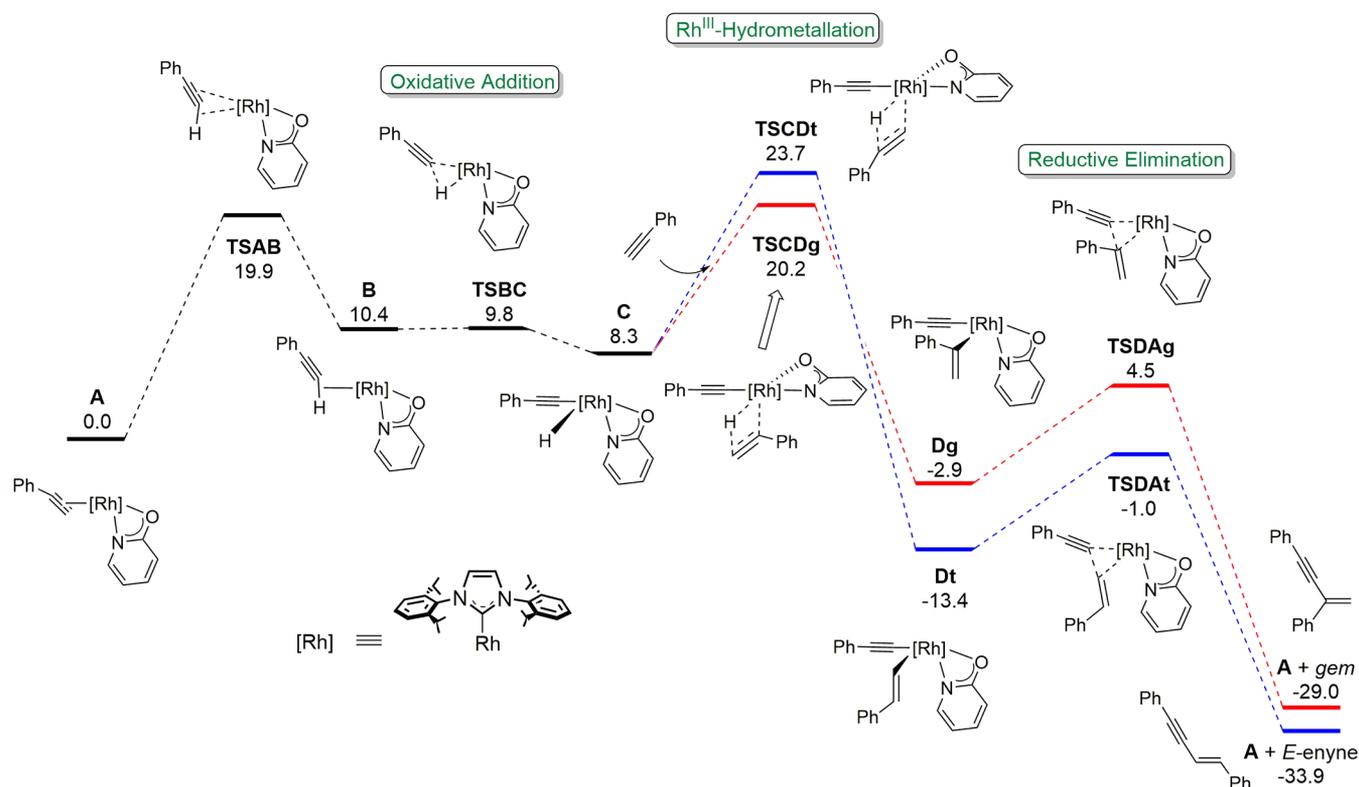

Figure 3. DFT calculations (ΔG in kcal·mol⁻¹, relative to A and isolated molecules) along phenylacetylene dimerization following the oxidative addition, migratory insertion, and reductive elimination steps.

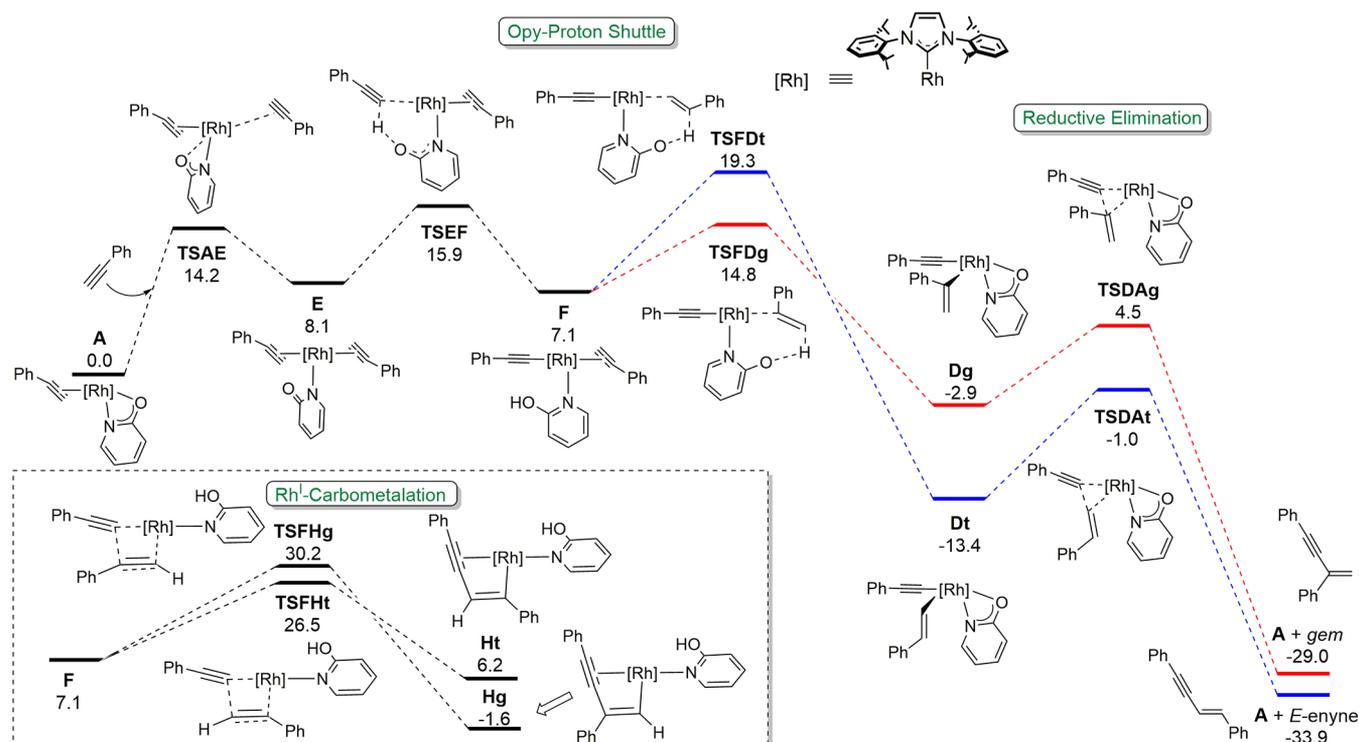

Figure 4. DFT calculations (ΔG in kcal·mol⁻¹, relative to A and isolated molecules) along phenylacetylene dimerization following the pyridonato-mediated proton shuttle and reductive elimination steps.

(Figure 4). However, these energetic barriers are higher than that computed for the oxidative route. An alternative pathway can be envisaged starting from the Rh^I-alkynyl intermediate F.

The κ^1 -*N*-hydroxypyridine ligand can now act as an intramolecular Brønsted acid able to transfer the proton to the remaining η^2 -alkyne of F to yield D.³³ Two possibilities arise

for this selectivity-determining step as the proton can be transferred to either the terminal or the substituted carbon atoms of phenylacetylene. Protonation of the external position via **TSFDg** (14.8 kcal·mol⁻¹), which ultimately leads to *gem*-enynes, is much more favored than the protonation of the internal one (**TSFDt**, 19.3 kcal·mol⁻¹). Alternative protonation reactions by the κ^1 -O- pyridin-2-one ligand in complex **G** are considerably more disfavored (see [Figure S104](#) in the Supporting Information). The catalytic cycle ends via alkenyl-alkynyl reductive elimination within **D** as previously analyzed. The concurrence of the **E** → **F** and **F** → **D** steps shows a very efficient cooperative Rh-pyridonato-mediated LAPS process. [Figure 4](#) shows that the higher energetic barrier corresponds to the CMD event (**TSEF**, 15.9 kcal·mol⁻¹), although those of the associative coordination of a second molecule of alkyne (**TSAE**, 14.2 kcal·mol⁻¹) or proton transfer (**TSFDg**, 14.8 kcal·mol⁻¹) are very close in energy, and thus, its contribution to the overall kinetics of the catalytic cycle might be not negligible. In order to evaluate the proposed mechanism for aliphatic alkynes, key structures were calculated considering propyne as a model system. An increment in the overall energy barrier from 15.9 to 17.7 kcal mol⁻¹ is observed which is in accordance with a lower catalytic activity (see [Table S3](#) in the Supporting Information).

As extracted from [Figure 4](#), the regioselectivity is controlled by the proton transfer to the alkyne, determined by a difference of 4.5 kcal·mol⁻¹ between the energetic barriers for the *gem*- and *E*-enynes. The origin of this selectivity can be explained by inspecting the NBO atomic charges in the intermediate **F** and the transition states **TSFDg** and **TSFDt** ([Figure 5](#)). Polar-

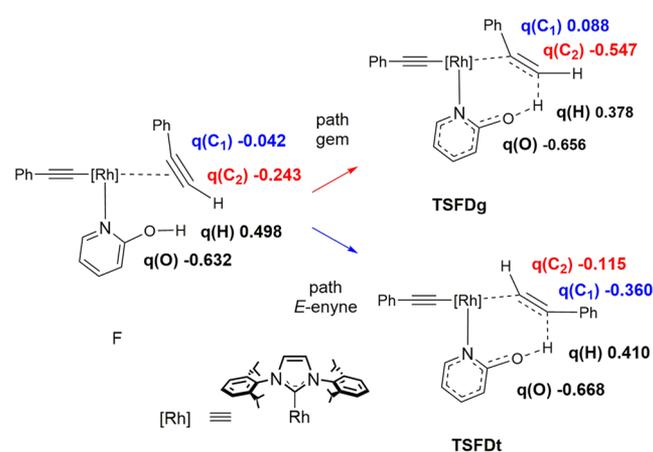

Figure 5. NBO atomic charges of atoms (in a.u.) involved in the proton transfer in structures **F**, **TSFDg**, and **TSFDt**.

ization of the coordinated alkyne in **F** was observed, showing a negative charge at the terminal carbon atom (−0.243e) larger than that at the internal position (−0.042e). Since the atomic charge of the hydrogen is +0.378e in **TSFDg** and +0.410e in **TSFDt**, the hydrogen migration can be considered formally a proton transfer, and not surprisingly, it will take place preferentially on the carbon bearing a larger negative charge, in this case the terminal carbon atom.

In order to understand the excellent catalytic performance of pyridonato complex **2** in comparison to similar amino-pyridinato (**3**) and mercapto-pyridinato derivatives (**5**), the energetic barrier for the CMD step has been calculated. Deprotonation by an oxygen atom is more efficient (15.9 kcal·

mol⁻¹) since the energetic barrier increases up to 22.5 and 26.5 kcal·mol⁻¹ for the NH or S substituents, respectively, in agreement with the experimental results (see [Figure S106](#) in the Supporting Information).

Mechanistic Considerations. Experimental and computational studies on the phenylacetylene dimerization catalyzed by **2** have revealed an operative metal–ligand cooperative mechanism as an alternative to the classical alkyne–C–H oxidative-addition or base mediated nonoxidative pathways ([Scheme 8](#)). The key point of this mechanism is the role of the Rh-pyridonato motif in the cooperative LAPS process. Initially, the hemilability of the ligand²¹ is essential to promote a κ^1 -N coordination mode which triggers the CMD step. Then, the proton is transferred selectively to the terminal position of a coordinated alkyne to finally close the cycle via a fast alkynyl-alkenyl reductive elimination. Indeed, the step determining the selectivity also changes. The orientation of the alkyne relative to the Rh–X bond in the insertion step generally directs the selectivity in conventional pathways, although reductive elimination is essential in some cases.^{11h,j} Thus, the difficult stereoelectronic control on π -alkyne coordination usually results in a mixture of isomers. However, the selectivity in the LAPS mechanism is directed by a protonation event. Thus, the attack to the terminal position of the alkyne is favored by 4.5 kcal·mol⁻¹ due to the formation of the more stable substituted carbocation intermediate, therefore enhancing specific *gem*-enyne formation. The combination of nitrogen–oxygen atoms within a pyridinato framework seems essential, since amino or thio functionalities show a lower ability for the CMD step.

As far as the deuterium labeling experiments are concerned, the relative small KIE value of 1.67 ± 0.12 discards, in principle, a C–H bond cleavage in the rate-determining step. However, DFT calculations have revealed that the CMD step is the one with the higher energetic barrier. A rational explanation for this, at first view paradoxical result, arises from the analysis of the CMD transition state **TSEF** ([Figure 6](#)). Inspection of the geometrical parameters reveals an early transition state character, as indicated by the distances $d(\text{C}, \text{H})$ and $d(\text{O}, \text{H})$ of 1.14 and 1.66 Å, respectively. Hence, the η^2 -(C–H) agostic interaction component in this transition state is prevalent over the C–H cleavage, therefore explaining its moderate effect in the KIE value. In fact, the theoretically computed KIE for this step is 1.57, which agrees with the experimentally determined value (see [Table S1](#) in the Supporting Information).

CONCLUSION

A series of mononuclear square-planar $\text{Rh}\{\kappa^2\text{-X}_2\text{N}(\text{Xpy})\}(\eta^2\text{-coe})(\text{IPr})$ ($\text{X} = \text{O}, \text{NH}, \text{NMe}, \text{S}$) BHetA complexes have been prepared. Among them, the N,O-pyridonato derivative displays an outstanding catalytic activity for *gem*-specific alkyne dimerization reaching TOF_{1/2} values of up to 17 000 h⁻¹ at room temperature. The proposed mechanism entails a cooperative LAPS process followed by fast alkenyl-alkynyl reductive elimination, which boosts the catalytic activity by lowering the energy barrier from 5 to 10 kcal·mol⁻¹ compared to Rh^{III}-hydrometalation or Rh^I-carbometalation conventional pathways. Hemilability of the pyridonato moiety has been revealed to be essential for an efficient CMD rate-limiting step. Moreover, the change in the selectivity-determining step from insertion to protonation is responsible for the exclusive formation of *gem*-enynes. These results prompt us to extend

the underlying principles described herein to related C–C and C–heteroatom bond forming catalytic reactions via C–H activation.

EXPERIMENTAL SECTION

General Considerations. All reactions were performed with rigorous exclusion of air and moisture using Schlenk-tube

techniques and drybox when necessary. The organometallic precursor $[\text{Rh}(\mu\text{-Cl})(\text{IPr})(\eta^2\text{-coe})]_2$ (**1**) was prepared as previously described.³⁴ Chemical shifts (expressed in parts per million) are referenced to residual solvent peaks (^1H and $^{13}\text{C}\{^1\text{H}\}$), NH_3 (^{15}N), or CFCl_3 (^{19}F). Coupling constants, J , are given in Hz. Spectral assignments were achieved by combination of ^1H – ^1H correlation spectroscopy (COSY), $^{13}\text{C}\{^1\text{H}\}$ attached proton test (APT), and ^1H – ^{13}C heteronuclear single quantum correlation/heteronuclear multiple bond correlation (HSQC/HMBC) experiments.

Preparation of $\text{Rh}\{\kappa^2\text{-O,N-(Opy)}\}(\eta^2\text{-coe})(\text{IPr})$ (2a,b**).** A mixture of 2-hydroxypyridine (49 mg, 0.52 mmol) and $t\text{BuOK}$ (58 mg, 0.52 mmol) in 5 mL of THF was stirred for 30 min at r.t. Then, a solution of dinuclear complex **1** (300 mg, 0.24 mmol) in 10 mL of THF was added, and the resulting mixture was stirred for an additional 1 h at r.t. After removing the solvent in vacuo, the residue was dissolved in toluene (10 mL) and was filtered through celite. Then, the filtrate was evaporated to dryness. The addition of hexane at -40°C induced the precipitation of a yellow solid, which was washed with cold hexane (3×2 mL) and dried in vacuo. Yield: 236 mg (72%). Satisfactory elemental analysis could not be obtained. HRMS (ESI⁺): m/z calc for $\text{C}_{40}\text{H}_{54}\text{N}_3\text{RhO}$ ($M^+ - \text{coe} - \text{H}$) 583.2180 exp 583.2173. IR (cm^{-1} , ATR): 1598 $\nu(\text{OCN}_{\text{sym}})$, 1471 $\nu(\text{OCN}_{\text{asym}})$. NMR data evidenced the presence of two isomers **2a** and **2b** (80:20), in equilibrium. Data for complex **2a**: ^1H NMR (500.1 MHz, CD_2Cl_2 , 298 K): δ 7.51 (t, $J_{\text{H-H}} = 8.0$, 2H, $\text{H}_{\text{p-Ph-IPr}}$), 7.38 (d, $J_{\text{H-H}} = 8.0$, 4H, $\text{H}_{\text{m-Ph-IPr}}$), 7.19 (dd, $J_{\text{H-H}} = 5.2$, 1.9, 1H, $\text{H}_{6\text{-py}}$), 7.11 (ddd, $J_{\text{H-H}} = 8.6$, 6.9, 1.9, 1H, $\text{H}_{4\text{-py}}$), 6.97 (s, 2H, $=\text{CHN}_{\text{IPr}}$), 5.97

A solution of **2** (30 mg, 0.043 mmol) in toluene- d_8 at 243 K (0.5 mL, NMR tube) was treated with 2-ethynyl-1,3,5-trimethylbenzene (21 μL , 0.129 mmol). NMR spectra were recorded immediately at low temperature. ^1H NMR (300.1 MHz, toluene- d_8 , 298 K): δ 7.5–6.5 (m, 10H, H_{Ph}), 6.80 (m, 1H, $\text{H}_{5\text{-py}}$), 6.65 and 6.62 (both br, 2H, $=\text{CHN}_{\text{IPr}}$), 5.76 (dt, $J_{\text{H-H}} = 8.5, 1.1, 1\text{H}, \text{H}_{6\text{-py}}$), 5.54 (ddd, $J_{\text{H-H}} = 6.8, 5.3, 1.0, 1\text{H}, \text{H}_{4\text{-py}}$), 5.25 (dt, $J_{\text{H-H}} = 5.3,$

1.1, 1H, H_{3-py}), 3.97, 3.95, 3.50, and 2.85 (all sept, J_{H-H} = 6.7, 4H, CHMe_{IPr}), 3.27 and 3.07 (both dd, J_{H-H} = 2.2, J_{H-Rh} = 1.0, 2H, CH_{2-π-ene}), 2.3–2.0 (18H, Me_{π-ene}), 1.80, 1.57, 1.55, 1.30, 1.14, 1.11, 1.08, and 1.02 (all d, J_{H-H} = 6.7, 24H, CHMe_{IPr}). ¹³C{¹H}-APT NMR (75.5 MHz, toluene-*d*₈, 243 K): δ 185.0 (d, J_{C-Rh} = 60.1, Rh–C_{IPr}), 181.4 (d, J_{C-Rh} = 2.7, C_{2-py}), 150.0, 148.2, 146.6, and 145.3 (all s, C_{q-IPr}), 142.4 (s, C_{3-py}), 142–134 (all s, C_{q-Ph-π-ene}), 139.0 (s, C_{5-py}), 138.9 and 137.1 (both s, C_{qN}), 131–123 (all s, CH_{Ph}), 128.4 (s, =CHN_{IPr}), 110.1 (s, PhC≡CC(Ph)=CH₂), 109.8 (s, C_{6-py}), 109.0 (s, C_{4-py}), 83.2 (s, PhC≡CC(Ph)=CH₂), 50.3 (d, J_{C-Rh} = 17.9, =CH₂), 41.0 (d, J_{C-Rh} = 17.8, C=CH₂), 30.3, 29.4, 28.8, and 28.7 (all s, CHMe_{IPr}), 29–20 (all s, Me_{π-ene}), 28.4, 28.3, 26.8, 26.6, 24.0, 23.5, 23.4, and 21.6 (all s, CHMe_{IPr}).

In Situ Formation of Rh{κ¹-O{-O=C(-CH=CH-CH=CH-NH)}[κ¹-O(-CF₃O₃S)](η²-coe)(IPr) (8a, 8b). A solution of 2 (23 mg, 0.033 mmol) in CD₂Cl₂ at 223 K (0.5 mL, NMR tube) was treated with trifluoromethanesulfonic acid (3 μL, 0.033 mmol). NMR spectra were recorded immediately at low temperature. NMR data evidenced the presence of an equilibrium mixture of two isomers, 8a and 8b (50:50). Data for complex 8a: ¹H NMR (400.1 MHz, CD₂Cl₂, 223 K): δ 11.73 (s, 1H, NH), 7.8–7.1 (m, 6H, H_{Ph,IPr}), 7.67 (m, 1H, H_{6-py}), 7.52 (m, 1H, H_{4-py}), 7.06 (s, 2H, =CHN_{IPr}), 6.85 (d, J_{H-H} = 9.0, 1H, H_{3-py}), 6.43 (m, 1H, H_{5-py}), 3.55 and 2.75 (both sept, J_{H-H} = 6.8, 4H, CHMe_{IPr}), 2.9–2.7 (m, 2H, =CH_{coe}), 1.6–1.0 (m, 36H, CH_{2-coe} and CHMe_{IPr}). ¹³C{¹H}-APT NMR (100.6 MHz, CD₂Cl₂, 223 K): δ 177.0 (d, J_{C-Rh} = 62.1, Rh–C_{IPr}), 165.2 (s, C_{2-py}), 147.0 and 146.9 (both s, C_{q-IPr}), 142.7 (s, C_{4-py}), 136.1 (s, C_{qN}), 135.9 (s, C_{6-py}), 130–123 (all s, CH_{Ph-IPr}), 120.0 (s, C_{3-py}), 109.7 (s, C_{5-py}), 66.9 (d, J_{C-Rh} = 14.0, =CH_{coe}), 33–25 (all s, CH_{2-coe}), 29.0 and 28.4 (both s, CHMe_{IPr}), 26.2, 22.5, 22.2, and 22.0 (all s, CHMe_{IPr}). ¹H–¹⁵N HMQC NMR (40.5 MHz, C₆D₆, 233 K): δ 174.0 (NH_{py}). ¹⁹F NMR (282.3 MHz, CD₂Cl₂, 223 K): δ –77.9 and –79.2 (both br, CF₃). Data for complex 8b: ¹H NMR (400.1 MHz, CD₂Cl₂, 223 K): δ 10.97 (s, 1H, NH), 7.8–7.1 (m, 6H, H_{Ph,IPr}), 7.37 (m, 1H, H_{6-py}), 7.30 (m, 1H, H_{4-py}), 7.06 (s, 2H, =CHN_{IPr}), 6.45 (m, 1H, H_{3-py}), 6.43 (m, 1H, H_{5-py}), 2.66 and 2.27 (both br, 4H, CHMe_{IPr}), 2.9–2.7 (m, 2H, =CH_{coe}), 1.6–1.0 (m, 36H, CH_{2-coe} and CHMe_{IPr}). ¹³C{¹H}-APT NMR (100.6 MHz, CD₂Cl₂, 223 K): δ 177.0 (d, J_{C-Rh} = 62.1, Rh–C_{IPr}), 164.6 (s, C_{2-py}), 146.0 (s, C_{q-IPr}), 142.5 (s, C_{4-py}), 135.5 (s, C_{qN}), 135.1 (s, C_{6-py}), 130–123 (all s, CH_{Ph-IPr}), 119.9 (s, C_{3-py}), 108.6 (s, C_{5-py}), 66.9 (d, J_{C-Rh} = 14.0, =CH_{coe}), 33–25 (all s, CH_{2-coe}), 29.0 and 28.4 (both s, CHMe_{IPr}), 26.2, 22.5, 22.2, and 22.0 (all s, CHMe_{IPr}). ¹H–¹⁵N HMQC NMR (40.5 MHz, CD₂Cl₂, 223 K): δ 170.3 (NH_{py}). ¹⁹F NMR (282.3 MHz, CD₂Cl₂, 223 K): δ –77.9 and –79.2 (both br, CF₃).

Standard Conditions for the Catalytic Alkyne Dimerization. To a C₆D₆ solution (0.5 mL) in a NMR tube under argon atmosphere, 0.01 mmol of catalyst and 0.17 mmol of toluene as internal standard were added. The solution was frozen by means of a dewar flask containing isopropanol at 195 K. Then, 0.50 mmol of alkyne were added and the NMR tube was sealed under argon. The solution was allowed to warm up to room temperature just before the first NMR spectrum was recorded. The reaction course was monitored by ¹H NMR spectroscopy, and the conversion was determined by integration of the corresponding resonances of the internal standard and the products. In case of 0.5, 0.1, or 0.05 mol % of catalyst loading, a 20 mM solution of catalyst in C₆D₆ was prepared, and then, the corresponding amount of solution was

added to the reaction mixture and it was proceeded as described above.

Crystal Structure Determination. Single crystals of 2 suitable for the X-ray diffraction studies were grown by slow diffusion of hexane into a toluene solution of the compound. X-ray diffraction data were collected at 100(2) K on a Bruker APEX SMART CCD diffractometer with graphite-monochromated Mo–Kα radiation (λ = 0.71073 Å) using 0.6° ω rotations. Intensities were integrated and corrected for absorption effects with SAINT-PLUS³⁵ and SADABS³⁶ programs, both included in the APEX2 package. The structures were solved by the Patterson method with SHELXS-97³⁷ and refined by full matrix least-squares on F² with SHELXL-2014,³⁸ under WinGX.³⁹

Crystal Data and Structure Refinement for 2. C₄₀H₅₄N₃ORh, 695.77 g mol⁻¹, Monoclinic, P2₁/c, a = 11.2672(10) Å, b = 10.7013(10) Å, c = 29.775(3) Å, β = 90.3070(10)°, V = 3590.0(6) Å³, Z = 4, D_{calc} = 1.287 g cm⁻³, μ = 0.510 mm⁻¹, F(000) = 1472, θ_{min}/θ_{max} = 1.807/25.680°, index ranges –13 ≤ h ≤ 13, –13 ≤ k ≤ 13, –36 ≤ l ≤ 36, reflections collected/independent 36521/6806 [R(int) = 0.0410], data/restraints/parameters 6806/13/452, GooF(F²) 1.041, R₁ = 0.0282 [I > 2σ(I)], wR₂ = 0.0635 (all data), largest diff. peak/hole 0.350/–0.422 e.Å⁻³. CCDC deposition number 2015873.

Computational Details. All DFT theoretical calculations were carried out using the Gaussian program package.⁴⁰ The B97D3 exchange correlation functional⁴¹ has been employed for the calculation of energies, gradients, and frequencies in combination to the def2-SVP basis set⁴² which considers effective core potentials for Rh. Single point calculations at the M06L/def-TZVP level of theory,⁴³ including also the SMD approach⁴⁴ for benzene to simulate solvation effects were performed to refine the energetic values. All calculations were done using the “ultrafine” grid. Relative energies are Gibbs free energies referred to a 1 M standard state using the approximation of Goddard et al.⁴⁵ at 25 °C. Analytical frequency analyses were employed to confirm the nature of the stationary points. An intrinsic reaction path or coordinate scan calculations connecting both minima were performed for flat or unclear transition states.

ACKNOWLEDGMENTS

Financial support from the Spanish Ministerio de Ciencia e Innovación (MICINN/FEDER) under the Projects PID2019-103965GB-I00 and PGC2018-099383-B-I00, and the Diputación General de Aragón (FEDER 2014-2020 “Building Europe from Aragón”, group E42_20R) are gratefully acknowledged. A.D.G. thanks the Spanish Ministerio de Economía y Competitividad (MINECO) for the postdoctoral grant Juan de la Cierva - Incorporación 2015 (IJCI-2015-27029). A.U. thankfully acknowledges the Spanish MECED for a FPU fellowship (FPU 2017/05417). The authors would like to acknowledge the use of Servicio General de Apoyo a la Investigación-SAI, Universidad de Zaragoza and the computational resources provided by the Institute for Biocomputation and the Physics of Complex Systems (BIFI)–Universidad de Zaragoza.

DEDICATION

Dedicated to Prof. Pierre H. Dixneuf, a very active species who initiated the catalytic cycles of many researchers.
