Abstract

The Quaternary deposits of the Ebro Basin in the surroundings of Zaragoza (Spain) form an unconfined alluvial aquifer with a high degree of permeability and low thickness of unsaturated materials. This fact causes a high degree of vulnerability to contamination which implies consequences for land-use decisions and the risk management of existing industrial facilities. In addition, in the last decades the intense irrigation and the use of pesticides is threatening the quality of the groundwater and as a consequence the amount of usable groundwater at a low cost. Thus, the development of groundwater vulnerability maps have great importance in a regional planning process.

Consequently, groundwater vulnerability maps have been developed following a method proposed by the German State Geological Surveys. In this paper the methodology developed within ArcGIS and Gocad, a two dimensional and three dimensional software, respectively, is presented. Although the results obtained within GIS (Geographical Information System) are acceptable it is to say that the 3D model improves considerably the final product.

Keywords: groundwater; geo-hazards; GIS; Gocad; Ebro Basin; Spain

Introduction

The city of Zaragoza is located in the central Ebro Basin (Spain). It is crossed by the Ebro river and two of its main tributaries, the Gállego and Huerva rivers (Figure 1). This is one of the reasons of its fast urban and industrial development

1
2
3 during the last decades: existence of superficial and ground water in addition to its
4
5 strategic position in the middle of four dynamic economic axes within the Iberian
6
7 Peninsula.
8
9

10
11 In the area between Jalón and Ginel rivers, tributaries of the Ebro river located
12
13 upstream and downstream Zaragoza respectively, the fluvial terraces formed by
14
15 the Ebro represent a substantial groundwater resource that should be preserved for
16
17 future generations.
18
19

20
21 Figure 1: Map of the study area.
22
23

24 In the last decades, the importance of this resource as a driving force for economic
25
26 development of urban areas all over the world caused the introduction of
27
28 groundwater vulnerability maps in many studies oriented to land-use management
29
30 under geo-environmental aspects (Cendrero et al. 1990; Dai et al. 2001; de Mulder
31
32 and Hillen 1990; Lerch and Hoppe 2006; Wolden and Erichsen 1990).
33
34

35
36 In this sense, a first step to carry out is vulnerability mapping. Definitions for the
37
38 following types of groundwater vulnerability have been proposed by COST Action
39
40 620 (COST Action 65 1995).
41
42

- 43 - Intrinsic vulnerability is the term used to define the vulnerability of
44
45 groundwater to contaminants generated by human activities. It takes into
46
47 account the geological, hydrological and hydrogeological characteristics of an
48
49 area, but is independent of the nature of the contaminants.
50
51
- 52 - Specific vulnerability is the term used to define the vulnerability of
53
54 groundwater to particular contaminants or group of contaminants.
55
56

57
58 If a revision of methodologies is made, it can be observed that most models deal
59
60 with intrinsic vulnerability. They usually apply qualitative weighting methods and

1
2
3 the main factor are related to the geological, hydrological and hydrochemical
4 characteristics of the aquifer and the materials above it.
5
6

7
8 An example is the DRASTIC system developed by Aller et al. (1987) which
9
10 considers the more important mappable technical parameters (factors) that affect
11 groundwater pollution potential: depth to water (D), net recharge (R), aquifer
12 media (A), soil media (S), topography (slope) (T), impact of the vadose zone (I),
13 and conductivity of the aquifer (C).
14
15
16
17
18

19
20 Fobe and Goossens (1990) developed a groundwater vulnerability map for the
21 Flemish Government. This map, in scale 1/100,000, was based on static factors,
22 like the lithology of the aquifer and its possible cover layers and the depth of the
23 water table.
24
25
26
27
28

29
30 Cendrero et al. (1990) identified and mapped “integrated units” (homogeneous
31 units) in Canarias and Valencia (Spain). Afterwards this areas of descriptive
32 nature were evaluated to obtain diagnosis maps of groundwater vulnerability
33 based on lithological characteristics and thickness of saturated zone.
34
35
36
37
38

39
40 Finally, based on the DRASTIC system and the addition of data from variables
41 such as land use/land cover to the rest of variables applied in the mentioned
42 method, Fritch et al. (2000) applied subjective numerical weightings according to
43 each variable’s relative importance in groundwater pollution susceptibility in
44 Paluxy aquifer in Central Texas (United States).
45
46
47
48
49

50
51
52 All these methods are applicable to all types of aquifers, but they do not
53 adequately take into account the special properties of karst aquifers. Methods like
54 EPIK (Doerfliger 1996; Doerfliger and Zwahlen 1998) and REKS (Malik and
55 Svasta 1999) were specially developed for karst.

Goldscheider et al. (2000) suggested that a method for vulnerability mapping at catchments scale should be applicable for all types of aquifers as well as take into account the special features of karst. Here, a general approach proposed by the German State Geological Surveys (GLA- Geologisches Landesamt- method) proposed by Hölting et al. (1995) is applied. It deals with intrinsic groundwater vulnerability and considers karstic conditions of the study area which give rise to vulnerabilities.

Methodology

The basic idea of Hölting et al. (1995) is that the effectiveness of all natural processes in the protective cover for reducing contaminant concentration is mainly dependent on the travel time. As a consequence, the protective function is dependent on the main factors which control the travel time: the thickness of each stratum and the properties of the materials (Goldscheider et al. 2000).

In relation to this, the protective function of the upper soil is assessed according to its effective field capacity (B value).

In the case of the subsoil, the protective function is obtained as follows: the value for the protective function of each stratum above the water table (G value) is multiplied by the thickness of that stratum (M value).

Afterwards the protective values of the soil and subsoil are added and multiplied by a factor reflecting the amount of recharge (W value), as shows the following formula:

$$S = (B + (\sum M * G)) * W \quad (1)$$

1
2
3 An additional protective function term can be included for artesian conditions and
4
5 for a perched aquifer above the aquifer in question. These conditions are not
6
7 present in the study area so these two factors are not included in the model.
8
9

10 The final value is called “protective function, total score” and it is classified into
11
12 five categories, from very low to very high protection, based on experience (Table
13
14
15 1).
16
17

18 Table 1: Classification of protective function total scores (after Hölting et al., 1995).
19
20

21
22 It was our intention to compare the results of applying this model completely in a
23
24 Geographical Information System (GIS) (the used GIS is ArcGIS 9.1 by ESRI
25
26 2005), hence in a 2D environment, or using a 3D software, Gocad (Earth Decision
27
28 Sciences 2005). This program was previously used to create a 3D geological
29
30 model for the study area (see Lamelas et al. 2006).
31
32
33

34 In the GLA method the recharge can be estimated from precipitation and
35
36 evapotranspiration values, but, in the study area, annual evapotranspiration
37
38 exceeds annual precipitation, so the annual recharge of the aquifer is highly
39
40 influenced by irrigation water. As a consequence two vulnerability maps were
41
42 developed: one taking into consideration the irrigation amount; another only
43
44 including the natural conditions of the area. This process was made twice, inside
45
46 ArcGIS 9 and Gocad, so finally 4 different models are presented.
47
48
49
50

51 52 **Results** 53 54

55
56 The basic difference between the groundwater vulnerability assessment based on
57
58 GIS and the solution provided with Gocad is that the latter approach takes full
59
60 advantage of the 3 dimensions of the subsurface. However there are some aspects

1
2
3 that necessarily should be performed within GIS and later on are introduced in the
4
5 Gocad process. These refers to the protective function of the upper soil (B value),
6
7 the amount of recharge (W value) and the water table model. In this section, first
8
9 the development process of these three models is explained to enter afterwards
10
11 deeper in the groundwater vulnerability maps developed within GIS and Gocad.
12
13
14
15

16 **The protective function of the upper soil: the B value**

17
18
19 For the assessment of the effective field capacity of the soil the information from
20
21 the Microleis system (de la Rosa and Magaldi 1982) was used. This system
22
23 includes a relationship between different textures of the soils and field capacities
24
25 that was developed for Mediterranean soils from a huge database.
26
27
28

29
30 Previously and following a geosystemic point of view of the Landscape Science, a
31
32 morpho-edaphic unit map had been created (Figure 2). Its basis were the landscape
33
34 units (Lamelas et al. 2006).
35

36
37 The information about texture of soils was extracted from several studies carried
38
39 out in the area at a more detailed scale (Machín and Navas 1994, 1995, 1998). The
40
41 different morpho-edaphic units with their effective field capacity and
42
43 corresponding B value are presented in table 2. For the regionalisation of this
44
45 values see Figure 3.
46

53
54
55

56 **The amount of recharge: the W value**

57
58 Precipitation and evapotranspiration models for the study area have been
59
60 developed using information from the National Meteorological Institute (INM,

1
2
3 Instituto Nacional de Meteorología). This information belongs to a series of 50
4
5 years data from 1940 to 1990 filled by means of one of the most complex, feasible
6
7 and strict methods for monthly data analysis and fill, Monthly Streamflow
8
9 Simulation Computer Program, developed by the Hydrologic Engineering Centre
10
11 from the Corps of Engineers in USA, commonly known as MOSS-IV (MOPT
12
13 1993, 1996). This covers the requirements of the W.M.O. (World Meteorological
14
15 Organization) that determine a minimum of 30 years period of measurements for
16
17 characterizing a climatic variable as precipitation and evapotranspiration (W.M.O.
18
19 1967). The data about evapotranspiration was obtained with the Thornthwaite
20
21 (Thornthwaite 1948) method that only needs data about the mean monthly
22
23 temperature to be calculated.
24
25
26
27
28

29
30 Later, this information has to be interpolated in order to obtain a continuous
31
32 surface for the project area. Interpolation procedures can be simple mathematical
33
34 models (inverse distance weighting, trend surface analysis, Thiessen polygons,
35
36 etc.), or more complex models (geostatistical methods, such as kriging and thin
37
38 plate splines). Here, the poor amount of climatic stations with long period data (9
39
40 and 7 for evapotranspiration and precipitation respectively) and their
41
42 heterogeneous distribution along the study area (see Figure 4) was a handicap for
43
44 the regionalisation of the meteorological data. This problem was solved by
45
46 enlarging the area to be interpolated (with 27 and 51 evapotranspiration and
47
48 precipitation stations respectively) and the use of a global methodology, a multiple
49
50 regression analysis between the meteorological variables and continuous
51
52 geographical variables (altitude, latitude, continentality, solar radiation).
53
54
55
56
57
58

59
60 Figure 4: Map of the locations of meteorological stations.

1
2
3 This deterministic method used by several authors (Ninyerola et al. 2000; Vicente
4 and Saz-Sánchez 2002) can be seen as an alternative to classical interpolation
5 techniques when spatial information is available. In this case, the following spatial
6 information has been chosen: altitude extracted from the Digital Elevation Model
7 of 20 m spatial resolution (M.A.P.A. 1997), latitude represented by the y
8 coordinate, longitude represented by the x coordinate, continentality represented
9 by the distance to Mediterranean and Cantabric Seas and finally, only in the case
10 of the evapotranspiration, the solar radiation. These factors were introduced in a
11 multiple regression analysis using a stepwise method.
12
13
14
15
16
17
18
19
20
21
22
23

24
25 After verifying all the assumptions of a multiple regression (normality, linearity
26 and homoscedasticity) and applying the subsequent transformations to the data,
27 the distance to Mediterranean Sea and the elevation above sea level were the two
28 variables introduced in both precipitation and evapotranspiration models.
29
30
31
32
33

34
35 Afterwards both models were performed in ArcGIS calculator to obtain the final
36 precipitation and evapotranspiration continuous surfaces (Figure 5).
37
38

39
40 Under natural conditions (without irrigation) as the precipitation is lower than
41 evapotranspiration all the area takes the highest W value implying high
42 protection. However, for the recharge under irrigation conditions also an
43 approximation to the irrigation amount was performed.
44
45
46
47
48

49
50 A data base with the available water resources assigned by the Ebro River
51 Authority (*Confederación Hidrográfica del Ebro, CHE*) to every Agrarian
52 Administrative Division (*Comarca agraria*) and irrigation system was available
53 (Cruz et al. 1997).
54
55
56
57
58

59 Besides, a cartography of irrigated areas with information about irrigation systems
60 developed by CHE is available from

1
2
3 <http://oph.chebro.es/ContenidoCartoRegadios.htm>. This map was combined with
4
5
6 the Agrarian Administrative Division Map (Comarcas map), and the values of
7
8 water availability were assigned to every system in every Comarca. It should be
9
10 noted that this is only an approach to the real water supply by irrigation as it
11
12 shows the maximum water availability under regular conditions without taking the
13
14 dry periods into account.
15
16

17
18 Figure 6 shows the recharge values after adding precipitation and irrigation and
19
20 subtracting evapotranspiration and the W value for the model taking irrigation into
21
22 account.
23
24

25
26 Figure 5: Mean annual precipitation and evapotranspiration models.

27
28 Figure 6: Recharge amount and W value under anthropic conditions.
29

30 **The water table model**

31
32
33 For the determination of the unsaturated zone a model of the water table is needed
34
35 so that the layers which are going to take part in the protective function can be
36
37 specified.
38

39
40 The information about water table level was obtained from the Water Points
41
42 Inventory (spa. *IPA*) of the Ebro Basin Authority (CHE). In this case, only the
43
44 points with more than 10 measurements were selected. The mean (irrigation
45
46 conditions) and minimum (without irrigation) water table level values were
47
48 queried from the database and interpolated with ordinary kriging. Figure 7 shows
49
50 both water table models.
51
52

53
54
55 Figure 7: Water table models.
56

57 **The Groundwater vulnerability within GIS**

58
59
60 Figure 8 shows a sketch of the working steps within GIS. First of all, two maps
have to be developed: the protective function of the soil (B value) and subsoil

1
2
3 (M*G value), respectively. Then, an addition of both maps is performed with the
4
5 raster calculator of the GIS. Afterwards, the result is multiplied by the aquifer
6
7 recharge mapping created (W value) following formula 1.
8
9

10
11 Figure 8: Scheme of the Groundwater vulnerability model (after Hölting et al., 1995) developed
12
13 within GIS.

14
15 Consequently, for the development of the model within GIS, the protective
16
17 function of the subsoil in the unsaturated zone have to be performed. The
18
19 unsaturated zone subsoil, consisting of granular, non-lithified material, is the layer
20
21 below the topsoil and above the water table. Its protective function is calculated
22
23 according to its grain-size distribution, which is also related to its permeability and
24
25 its thickness (M*G value).
26
27

28
29 The information of subsoil was obtained from the *IPA*. This information was
30
31 completed with several boreholes collected from different private enterprises
32
33 (Control-7, Entecsa, Z-amaltea, CTA, ESHYG) and from some previous studies
34
35 carried out for the construction of several roads (M.O.P. 1967, 1970, 1973, 1994,
36
37 2000, 2003). Figure 9 shows the heterogeneous location of the boreholes in the
38
39 alluvial and the lack of information mainly in the area downstream Zaragoza, thus
40
41 determining a worse quality of the model in this area.
42
43
44
45

46
47 Figure 9: Location of the boreholes in the alluvial aquifer.
48
49

50
51 In Tables 3 are presented the different protective values assigned to different
52
53 description of subsoil stratum. The protective function of every borehole is
54
55 calculated, as explained before, by multiplying the protective function of every
56
57 stratum by its thickness and summing up all the strata values above the water
58
59 table. This value has to be calculated twice as the water table varies from natural
60

1
2
3 conditions (that is without taking into account irrigation) to anthropologic and
4
5 actual conditions (taking irrigation into account; Figure 10).
6
7

8 Afterwards, the protective values of the boreholes are interpolated. In this case a
9
10 simple kriging interpolation within the GIS has been used to obtain two
11
12 continuous surfaces, one taking into account irrigation water and another under
13
14 natural conditions without irrigation (Figure 10). The final groundwater
15
16 vulnerability models are shown in Figure 11.
17
18

19
20 In the case of the groundwater vulnerability with irrigation, the model is highly
21
22 determined by the water recharge. Thus, the highest vulnerability values are
23
24 located in the lower terraces with irrigation land use. There are some exceptions,
25
26 i.e. the surroundings of El Burgo de Ebro, the north-west of Zaragoza and the
27
28 north of Alagón (Figure 1), where medium or low susceptibility values appear,
29
30 although irrigation is present. This usually occurs because of high protection
31
32 values of the subsoil, caused by high thickness of unsaturated Quaternary
33
34 sediments or high presence of impermeable layers in the lithological profile.
35
36 The values of protection improve considerably in the case of the model under
37
38 natural condition without support of water by irrigation. This model follows much
39
40 more clearly the tendency of the protective function of the subsoil, but with the
41
42 added circumstance of improving the values of protection, since, in the whole
43
44 area, the protective function of the subsoil is multiplied by 1.5 (due to the low
45
46 recharge). Thus, here again, the highest protective values are located in the areas
47
48 with higher thickness of unsaturated Quaternary sediments or areas with high
49
50 percentage of impermeable layers in the profile. It is remarkable the situation in
51
52 the north-east of Zaragoza, where relatively high thickness of unsaturated
53
54
55
56
57
58
59
60

1
2
3 sediments is present, but the vulnerability is high, due to the elevated permeability
4
5
6 of the layers.
7

17

18 **The groundwater vulnerability in Gocad**

19
20 A 3D approach requires some effort in terms of considering a variety of geometric
21
22 boundary conditions. In our case the geometric body under consideration is the
23
24 Quaternary. While the upper boundary of the Quaternary could be easily defined
25
26 with the Digital Elevation Model the lower boundary in terms of the Quaternary-
27
28 Tertiary border was constructed with the information of about 400 boreholes. To
29
30 fill the space in between the upper and lower boundary, Gocad offers the sGrid
31
32 object which is a collection of initially regularly spaced cells which fill the three
33
34 dimensions with information. However, a sGrid can be deformed such that it
35
36 perfectly suits geometrical boundary conditions. Figure 12 shows the definition of
37
38 a regular sGrid and its deformation by geometric constraints. Please note that all
39
40 sGrid cells outside the study area were declared as 'dead cells' thus indicating that
41
42 they are to be excluded from further computations.
43
44
45
46
47
48

49
50 Next, the geological body was filled with information. Therefore, the layers
51
52 encountered in the boreholes were assigned with a value taken from table 3 (G-
53
54 value). These G-values were then interpolated within the sGrid object thus filling
55
56 the 3D space. The interpolation method used was the discrete smooth interpolation
57
58 algorithm (DSI) which belongs to the core functionality of Gocad.
59
60

1
2
3 Besides the G value property a sGrid object can hold various other properties. To
4 keep all information which is needed for the groundwater vulnerability calculation
5 in one object, additional properties (B, W values) were added to the sGrid.
6
7

8
9 Moreover, help properties were introduced which helped to distinguish between
10 distinct areas. For instance a Boolean property was added which helped to
11 distinguish between layers above and below the groundwater table. All cells of the
12 sGrid above the groundwater table were given a value of 1 whereas the rest was
13 given a value of 0.
14
15

16
17 Then a script was applied on the sGrid, allowing a user defined computation of the
18 protective function for each column of the sGrid. Figure 13 shows the principle of
19 the computations where a groundwater recharge between 300-400 mm/a ($W=1$) is
20 assumed. The resulting value for each column was projected as a point on a flat
21 2D surface. This collection of points was then imported by ArcGIS and
22 transformed to a map representing the protective function of the unsaturated zone
23 or the ground water vulnerability respectively (Figure 14).

40 Figure 12: Gocad regular sGrid definition. a) top view of sGrid with outline of study area, b)
41 regular sGrid before deformation, c) lower and upper surfaces of Quaternary body, d) deformed
42 sGrid (vertical exaggeration factor: 50).
43
44

45 Figure 13: Example calculation for one column of a sGrid object. According to table 1, a value of
46 1160 is equal to a medium protective function of the unsaturated zone (after Lerch 2005).
47
48
49

50 The groundwater vulnerability with irrigation conditions model is also extremely
51 influenced by the recharge, as in the case of the model generated in ArcGIS. But,
52 within Gocad, this influence is highly smoothed by the 3D interpolation method.
53
54

55 In general, both results follow the same general tendency, however, the model
56 developed in ArcGIS presents lower protection values in some sectors where,
57 according to the Gocad model, the protection class is medium or even high. This
58
59
60

1
2
3 is the case of the meander at the west of Zaragoza. This sector presents relatively
4
5 high thickness of Quaternary deposits, high thickness of unsaturated materials and
6
7 a high percentage of impermeable layers. Thus, the Gocad model present in this
8
9 sectors more reliability protection values according to the characteristics of the
10
11 aquifer. Similar cases can be observed i.e. at the south-east of Casetas, at the north
12
13 east of Alagón in the confluence of the Jalón and Ebro Rivers and in the
14
15 surroundings of La Cartuja (downstream Zaragoza).
16
17

18
19 Greater differences are observed between the model developed under natural
20
21 conditions with Gocad and the one developed with ArcGIS. The latter tends to
22
23 exaggerate the protection in the lowest values of protection, and reduce the
24
25 protection in the highest values. An example of this situation can be observed in
26
27 the right bank of the Ebro River downstream El Burgo de Ebro. In this sector, low
28
29 thickness of unsaturated deposits and low percentage of impermeable layers are
30
31 present, thus implying very low protection values, as the Gocad model suggests,
32
33 and no medium and high protection values, as the ArcGIS model suggests.
34
35
36
37
38
39

40 Figure 14: Groundwater vulnerability maps developed within Gocad.
41

42 Discussion

43
44 One of the main advantages of the GLA method is the availability of the
45
46 information required for its performance as it only required general information
47
48 related to soils, climatology, geology and hydrogeology which is relatively easy to
49
50 obtain and introduce in the GIS.
51
52

53
54 The development of this methodology within GIS is relatively easy implying
55
56 simple interpolation between points in order to obtain two-dimensional
57
58 vulnerability maps. As a consequence, the three dimensional characteristic of the
59
60 aquifer is not considered. Therefore, groundwater vulnerability maps developed

1
2
3 within Gocad should generate more realistic results (although the final result is
4
5 also two-dimensional) as it takes the three-dimensional geological information
6
7 into account (Hoppe et al. 2006).
8
9

10 The models developed for our study area in the present-day conditions with
11
12 irrigation are extremely influenced by the recharge of the aquifer. However, in the
13
14 case of the model developed in Gocad, this influence is highly smoothed by the
15
16 3D interpolation method. In addition, the model developed in ArcGIS, in some
17
18 sectors, presented lower values of protection than the ones it should have
19
20 presented, according to the characteristics of the aquifer. Thus, although both
21
22 results follow the same general tendency, the Gocad models present, in general,
23
24 more reliability mapping. Besides, the Geographical Information System produces
25
26 less realistic results, showing strong discontinuities, normally less usual for
27
28 natural processes.
29
30
31
32
33

34 Under natural conditions without irrigation recharge, the model developed with
35
36 the Geographical Information System tends to exaggerate the protection in some
37
38 sectors, and to reduce it in other ones. Thus, when feasible, it is extremely
39
40 recommended to perform 3D approaches, although they are frequently more time
41
42 and money consuming.
43
44
45
46

47 Due to the lack of information downstream Zaragoza the reliability of the model
48
49 in this sector is certainly fairly low. However, with its limitations, the results
50
51 obtained are satisfactory as the groundwater vulnerability maps developed,
52
53 especially in the case of the three dimensional approach, are of great value for
54
55 land-use management at regional scales.
56

Table 2: B value for the different types of soil (after Hölting et al., 1995).

Soils/Properties	Effective field capacity mm/m	Hölting value
Haplic Gypsisols	225,2	500
Calcaric Cambisols	190,4	250
Petric Calcisols	190,4	250
Haplic Solonchaks	146,8	250
Calcaric Fluvisols	120,3	125
Calcaric Regosols	190,4	250

For Peer Review

Table 3: G value according to Hölting et al. (1995) for different stratum description.

Description boreholes	G value	Description boreholes	G value
R	8	A	25
C	5	A,G	10
C,G,Y	5	A,G,C	10
C,L	75	A,G,L	75
C,Y	5	A,G,Y	10
D,Y	5	A,L	75
G	5	A,L,G	75
G,M	50	A,L,K	75
G,A	10	A,Y	25
G,A,M	60	L	500
G,A,L	75	L,G	100
G,A,Y	10	L,G,K	100
G,L	75	L,K	100
G,L,A	75	L,K,G	100
V	0	L,M	100
K	5	L,M,Y	100
K,M	5	L,A	170
K,L	5	L,A,G	100
M	20	L,Y	200
M,G	20	L,Y,M	200
M,K	20	Y	5
M,A	20	Y,C	5
M,L	20	Y,G	5
M,L,Y	20	Y,M	5
M,Y	20	Y,H	5
M,Y,L	20	Y,L	5
S	1	Y,L,M	5
?	1		

A= sand, G= gravel, C= conglomerates, L= clay, M= marls, Y= gypsum, K= limestone, D= dolomite, H= halite, P= schist, S= soil, R= fillings, ?= unknown, V= cavity, DY= debris.
