Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.

9 **Abstract:** Nickel is capable of discharging electric and magnetic shocks in aerospace materials
10 thanks to its conductivity and magnetism. Nickel nanowires are especially desirable for such an
11 application as electronic percolation can be achieved without significantly increasing the weight
12 of the composite material. In this work, single-crystal nickel nanowires possessing a
13 homogeneous magnetic field are produced *via* a metal-organic precursor decomposition
14 synthesis in solution. The nickel wires are 20 nm in width and 1-2 μm in length. The high
15 anisotropy is attained through a combination of preferential crystal growth in the $\langle 100 \rangle$ direction
16 and surfactant templating using hexadecylamine and stearic acid. The organic template ligands
17 protect the nickel from oxidation, even after months of exposure to ambient conditions. These
18 materials were studied using electron holography to characterize their magnetic properties. These
19 thin nanowires display homogeneous ferromagnetism with a magnetic saturation ($517 \pm 80 \text{ emu}$
20 cm^{-3}), which is nearly equivalent to bulk nickel (557 emu cm^{-3}). Nickel nanowires were
21 incorporated into carbon composite test pieces and were shown to dramatically improve the
22 electric discharge properties of the composite material.

48 Lightning can and does strike the same place twice. In the case of airplanes, lightning hits each
49 plane on average once per year and enters almost exclusively through the nose. Spacecraft are
50 currently built of carbon fiber-reinforced composites, a material that is lightweight and has
51 desirable mechanical properties, however which suffers from low electrical conductivity.

1
2
3 Damage can be caused by low attenuation of electromagnetic radiation and electrostatic
4 discharge (*i.e.* lightning strikes),¹ creating a security risk in the spacecraft and requiring
5 expensive repairs. Typically, aluminum or copper are incorporated into the carbon fiber-
6 reinforced composites in order to quickly dissipate the charge. However, copper suffers from
7 oxidation and aluminum from galvanic corrosion. Nickel can effectively dissipate concentrated
8 magnetic and electrical fields, it is resistant to extensive oxidation thanks to the natural formation
9 of a passivating oxide, it has a reasonably low density and is comparatively inexpensive.
10 Conductive Composites sells nickel nanostrandsTM for aeronautics applications, which have been
11 proven to effectively shield composites from electromagnetic interference and electrostatic
12 discharge-induced damage even after 2 million cycles of fatigue loading.¹

27 Nickel nanostructures have been synthesized in a variety of shapes and sizes by employing
28 several chemical protocols,²⁻⁵ yielding nanomaterials with various physical properties. However,
29 this current report is the first solution based synthesis of individual monocrystalline nanowires.
30 Previously, monocrystalline nickel nanowires have been created via electrodeposition using
31 porous templates, with the smallest nanowire diameter produced to date being 50 nm.⁶ A similar
32 technique has been used to produce Au/Ni composite wires using a porous template with a 40 nm
33 diameter.⁷ Solution chemistry protocols have produced isotropic nanoparticles,⁸ short nanorods,⁴
34 a variety of other structures² and polycrystalline nanowires.^{9,10}

46 Monocrystallinity is important because conductivity is related to the number of grain
47 boundaries, as grain boundaries are a barrier to electrical transport.¹¹ Moreover, a protective
48 layer of nickel oxide forms typically upon exposure to air. Oxidized nickel can be either non-
49 magnetic or antiferromagnetic, radically decreasing the magnetization values compared to those

3 of pure fcc-nickel.¹² Long monocrystalline wires of metallic nickel are ideal materials for
4 applications that require high electrical conductivity and magnetization saturation.
5
6

7
8 We report the metal-organic synthesis of highly anisotropic nickel nanowires having no grain
9 boundaries. The Ni nanowires are obtained through the reduction of a nickel stearate complex
10 using hydrogen gas at 150 °C, in the presence of hexadecylamine and stearic acid (experimental
11 details in SI). The nanowires grow along a particular crystallographic axis (*i.e.* c), forming a
12 single-crystalline nanowire for the first time using solution chemistry techniques. Using the
13 appropriate relative concentrations of ligand and nickel precursor allowed us to increase the
14 length of the nanowires and to transition away from nanorod-based sea urchin structures. We
15 investigate the magnetic properties of these anisotropic structures using off-axis electron
16 holography and discuss the correlation of such properties with the nanowire structure. The
17 organic ligand layers capping the nickel nanowires protected them from oxidation.

31
32 The nickel nanostructures appear either as sea urchin-like structures or as highly anisotropic
33 nanowires, depending on the synthesis conditions (Figure 1, a movie showing the tomography
34 can be found as SI). Anisotropic structures can result from templating or from a difference in the
35 rate of crystal growth along a certain axis. A difference in crystallographic growth rate can occur
36 to minimize the surface energy¹¹ or from capping certain facets with surfactants, ions or
37 solvent.¹⁴⁻¹⁶ The sea urchin-like nanostructures are collections of individual nanowires growing
38 from a single nucleus.¹⁷ The predominance of a wire versus urchin morphology can be explained
39 using nucleation and growth kinetics, as has been seen in CoNi nano-objects.¹⁸ High nucleation
40 and growth rates led to CoNi nanowires, where slow nucleation and fast growth led to a sea
41 urchin morphology. The same likely applies to the nickel nanostructures presented here. When
42 the nickel precursor and ligand were highly diluted, nucleation was favored over growth and

1
2
3 spherical particles were produced (Figure 2). By decreasing the quantity of solvent, growth was
4 favored over nucleation, producing a dense sea urchin nanostructure (Figure 2b). Upon further
5 concentrating the solution, a less highly branched nanostructure was observed (Figure 2c), which
6 cannot be explained with nucleation and growth kinetics, but rather to surfactant organization
7 and templating effects. The stearic acid ligand played a major role in the formation of anisotropic
8 nanowires. In the absence of stearic acid, spherical particles were produced (Figure 1b). By
9 increasing the concentration of stearic acid, the anisotropy of the nanoparticles increased (Fig.
10 1c-d). In this later case, branched nanowires were still present, but unbranched nanowires were
11 commonly found. The nanowires were about 20 nm in width and up to 2 μm in length. Thus,
12 both crystal growth kinetics and surfactant templating seem responsible for the nickel
13 nanostructure morphology.

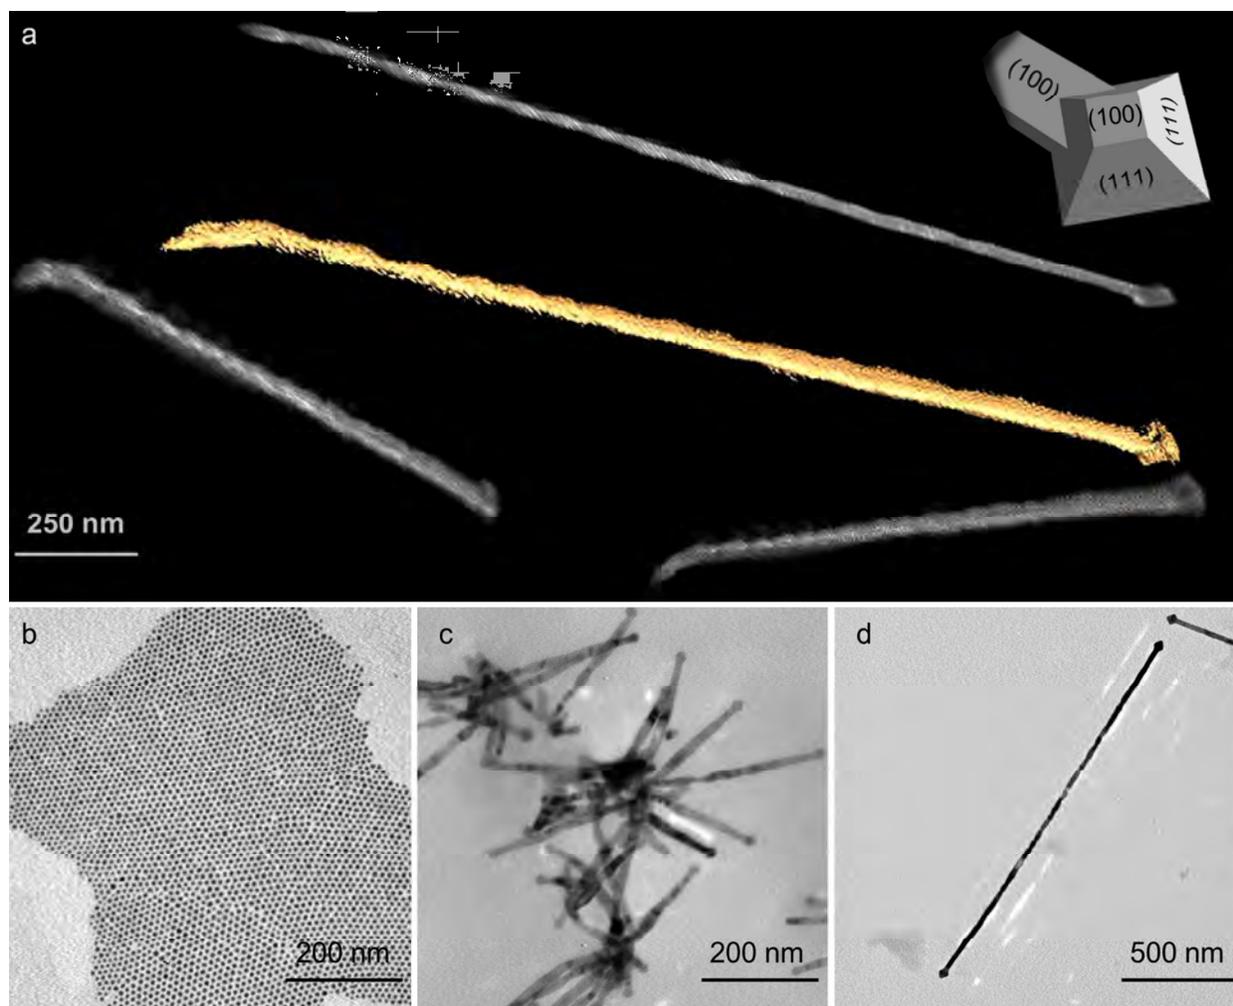

Figure 1. (a) TEM tomographic image of a nickel nanowire with shadows projected in the xy , xz and yz planes to show the morphology of the nanowire in 3D space. The crystallographic planes are indicated on the illustration in the upper right corner. Nickel nanostructures using a nickel precursor to stearic acid molar ratio of (b) 1:0, (c) 1:2 and (d) 1:6. The white contrast in (c) and (d) are “ghost” images arising from aberrations in the lenses: the corresponding images from diffracted and transmitted beams are displaced relative to one another.

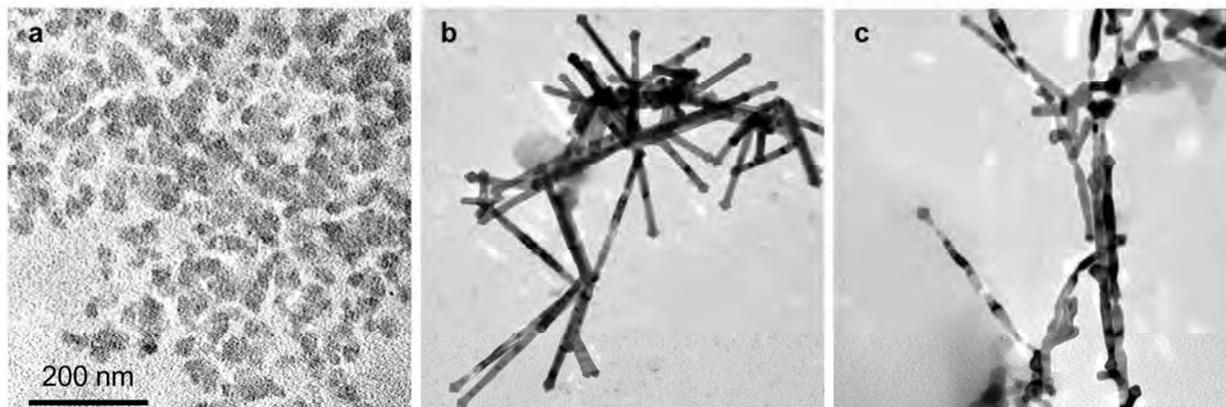

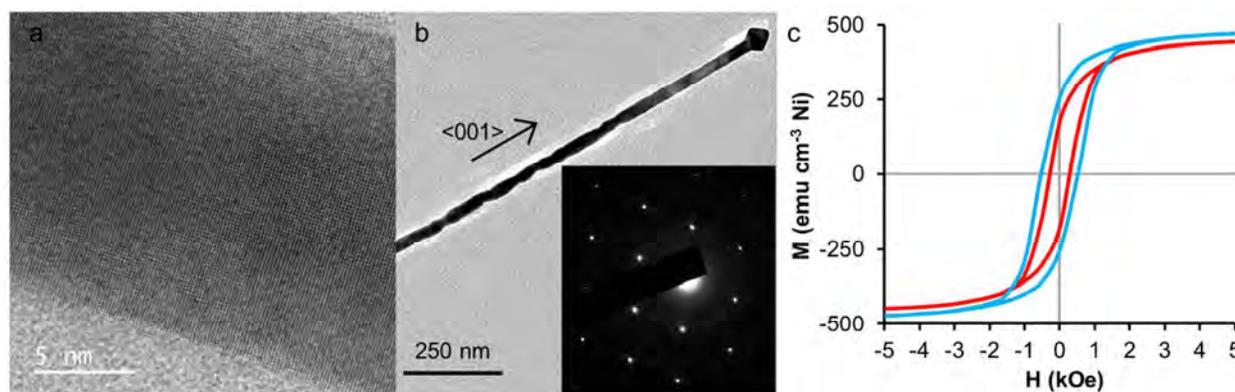

Figure 2. Nickel nanostructures prepared from nickel stearate dissolved in anisole at a concentration of (a) 5 mM, (b) 50 mM and (c) 150 mM. Under highly dilute conditions spheres appear, while individual nanowires are more prevalent under concentrated conditions. The nickel precursor to stearic acid molar ratio was 1:2. The scale is the same for all images.

The nickel nanowires terminate with a square pyramid tip, with faces of (111) crystallographic orientation, the natural extension of the $\langle 001 \rangle$ crystallographic lattice. The sea urchin shape with capped tips has been previously observed in CoNi nanostructures.^{17,18} The capped tips can be explained using growth kinetics.¹⁸ Towards the end of the synthesis, the nickel precursor is nearly consumed and the consequential drop in its concentration slows the particle growth rate significantly. Similarly for nickel nanoparticle growth, at the end of the reaction the extremely dilute conditions allow simultaneous growth along other axes, thus generating an arrowhead.

The nickel nanowires are monocrystalline, thus they grew continuously from a nucleus until the nickel precursor depleted (Figure 3a). By measuring the interplanar distances in the diffraction pattern, we determined that the nickel nanorods grew in the $\langle 001 \rangle$ direction, and thus the faces present (100) or (111) crystallographic planes. These planes minimize the surface energy.¹⁷ No grain boundaries, crystallographic defects or nickel oxide are visible in the

1
2
3 microscopy images (Figure 3a). Normally nickel forms a 2 nm passivating nickel oxide shell
4 upon exposure to air.²⁰ If a 2 nm crystalline oxide shell were present, the diffraction pattern
5 would show differences in the interplane distances between Ni and NiO (Figure 3b inset). The
6 diffraction pattern, which is characteristic of a single crystal lattice, was obtained for the 1085
7 nm long segment of the nanowire shown in Figure 3b and is representative of the other
8 nanowires analyzed. Thus, the representative TEM images and the associated diffraction pattern
9 prove the nanowires are monocrystalline, and lack a NiO passivating layer. It seems that the
10 organic ligands used are highly effective at protecting the surface from oxidation. Using TGA, it
11 was found that the organic ligands composed 6.8 wt% of the sample. Taking the surface area of
12 the Ni nanowires as $22.6 \text{ m}^2 \text{ g}^{-1}$ and assuming that the hexadecyl amine and the stearic acid form
13 ion pairs,²² the surface coverage is 6.9 ligand molecules/nm². This is an extremely high charge,
14 indicating that there is probably two or more layers of ligands protecting the nanowire.

1
2
3 nanowires was measured after 3 months of exposure to air. The coercivity H_c is 0.54 kOe at 2 K,
4
5 and 0.31 kOe at 300 K.
6
7

8
9 SQUID measurements show that the material presents ferromagnetic properties (Figure 3c).
10
11 The saturation magnetization at room temperature is equal to 460 emu cm^{-3} , slightly lower than
12
13 bulk nickel (557 emu cm^{-3}). This lower value may be due to the coordination of the stearic acid
14
15 to the nickel surface.⁴ SQUID measurements of the magnetism at 2 K and ambient temperature
16
17 also confirm the absence of oxidation. An oxide layer around nickel modifies its magnetic
18
19 properties.²² Nickel is ferromagnetic, where nickel oxide is antiferromagnetic. A thin shell of
20
21 NiO around a Ni core generates a temperature dependent exchange bias, observed as a horizontal
22
23 shift of the magnetic hysteresis loop.^{20,23} As the hysteresis loop corresponding to the field-cooled
24
25 measurement is not shifted along the H-axis, there is no detectable amount of NiO around the Ni
26
27 nanowires. The nickel nanowires show no evidence of surface oxidation even months after
28
29 preparation, stored under ambient conditions.
30
31
32
33
34

35
36 Magnetic and electric maps can be obtained by electron holography, which measures the phase
37
38 shift of the electron beam after interaction with the electromagnetic field of the sample. Electron
39
40 holography thus provides the high spatial resolution known to electron microscopy and a
41
42 quantitative analysis of the local magnetic configuration (Figure 4). The exact magnetic
43
44 configuration can thus be correlated to the structural properties of a nanostructure, such as the
45
46 crystal structure, grain boundaries, geometry, and defects. Electron holography measurements
47
48 can be used to reconstruct the 3D geometry of the nano-object. In our case, these correspond to
49
50 what was observed with electron tomography images (movie in supplementary information).
51
52 Electron holography proved that the nickel nanowires are ferromagnetic with a magnetization
53
54 laid along the nanowire axis due to shape anisotropy (Figure 4).^{24,25} An off-axis electron
55
56
57

1
2
3 holography experiment in the Lorentz mode was performed using a Hitachi HF 3300C
4 microscope operating at 300 kV and achieving a 0.5 nm spatial resolution in a field-free
5 magnetic environment (less than 10^{-3} T). All the holograms were recorded in a 2 biprism
6 configuration and the fringe spacing was set to 1.1 nm in this study. Phase and amplitude images
7 were extracted from the holograms using homemade software with a spatial resolution of 4 nm.
8
9

10
11
12 From the measured magnetic phase shift of 0.3 rad, we obtain a Ni magnetization of about
13 0.65 ± 0.1 T, *i.e.* 517 ± 80 emu cm^{-3} in agreement with values obtained from SQUID. The whole
14 nanowire demonstrated a homogeneous magnetism, although some nanowires exhibited domain
15 walls where the magnetism changed direction. The domain walls show 180° angular
16 displacement and may have been nucleated by saturating the sample during observation. The
17 domain walls were found to exist at the thinnest part of the nanowire, bearing in mind that the
18 nanowire is monocrystalline, but slightly irregular in width. The domain walls were in the form
19 of pure transverse walls, with no magnetization induction observed in the very center of the
20 domain wall. At this center the magnetization is either parallel to the +Z or -Z direction, as the
21 electron phase shift is only sensitive to the components perpendicular to the electron beam.
22 Vortex states are absent, even in the nanowire arrowheads. The anisotropy of the nanowire is
23 known to cause spin alignment in plane with the wire axis, creating a uniform magnetic state.²⁶

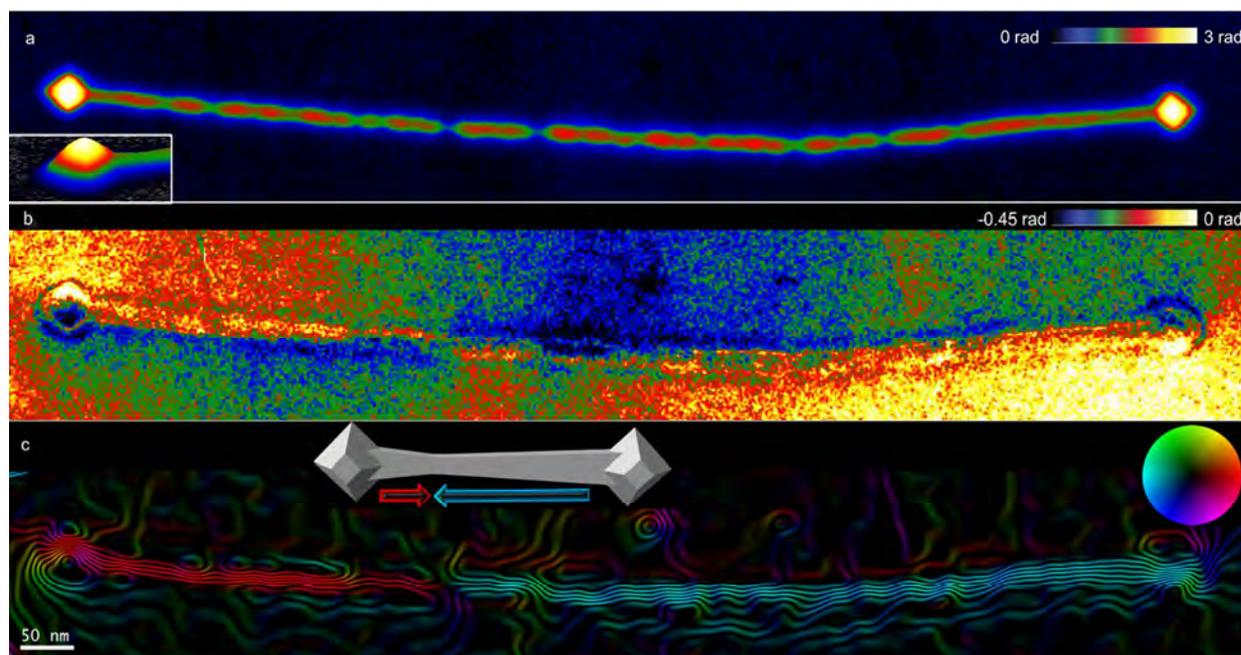

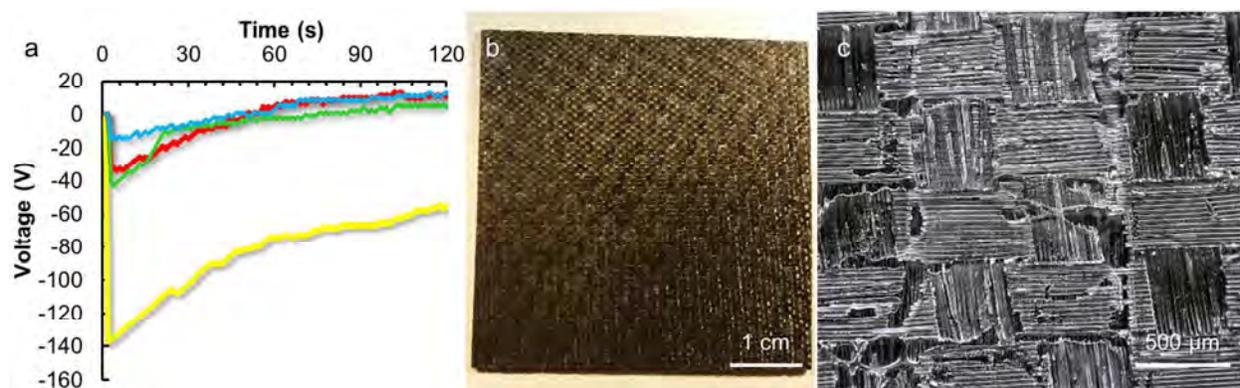

Figure 4. Electron holography of a single, isolated nickel nanowire showing: (a) The mean inner potential (atomic contribution), with an inset showing the height profile; (b) The magnetic phase @ 4 nm spatial resolution, with a measured phase shift of 0.3 rad in different points of homogeneous thickness across the nanowire; and (c) The vectorial map modulated by the cosine of the magnetic phase (amplified x180) showing a domain wall. The color indicates the direction of the magnetic field, indexed using the color wheel.

To study the electric dissipation of the nickel nanowires, they were dispersed in a polyamide epoxy resin at 0.5, 1 and 5 wt% relative to the quantity of resin, and then infiltrated into a carbon tissue (see supporting information for details). This composite was cured at 80 °C under vacuum, and then cut into test pieces using micromilling (Figure 5b, Figure S1). Potential decay measurements (Figure 5a, Figure S3) were performed on these test pieces to study how an applied surface charge is dissipated by the surface of the material. We can see in Figure 5a that the charge dissipation occurs much more quickly when nickel nanowires are incorporated into the resin relative to the non-doped carbon composite, which has a much higher concentration of

1
2
3 electrical charge. The quantity of charge at the beginning of the measurement is already inferior
4
5 for the nickel loaded samples, as the charge was largely dissipated during the charging phase.
6
7 The infiltration of the nickel-charged resin into the tissue was not perfectly homogeneous, as can
8
9 be seen in Figure 5c, which led to inhomogeneities in the dissipation measurements. However,
10
11 the measured trend was constant: with 5 wt% nickel nanowire loading, the dissipation was much
12
13 more efficient and complete within around 1 min.

In conclusion, we report the first solution-based synthesis of monocrystalline nickel nanowires. The nickel nanowires are 20 nm in diameter and up to 2 μm in length, and are synthesized via the decomposition of metal-organic compounds under air-free and water-free conditions. These nanostructures nucleated and then grew progressively in the $\langle 100 \rangle$ direction, where the anisotropy results from a combination of crystal growth kinetics and surfactant templating. There are no grain boundaries within the nanostructure. However, the nanowires are not perfectly homogeneous in width and the thinner portions are susceptible to the formation of magnetic

1
2
3 domain walls. Further experiments will show whether the magnetic domain wall was nucleated
4 during observation or whether it was naturally present within the wire. The intensity of the
5 magnetic response is constant and does not show any vortexes. We are currently studying the
6 aging properties of these nickel nanowires in the aerospace carbon composite test pieces, to
7 study the dissipation behavior upon electric and magnetic shocks with time and under
8 temperature and humidity variations.
