The over-expression and aggregation of α -synuclein (α Syn) are linked to the onset and pathology of Parkinson's disease. Native monomeric α Syn exists in an intrinsically disordered ensemble of interconverting conformations, which has made its therapeutic targeting by small molecules highly challenging. Nonetheless, here we successfully target the monomeric structural ensemble of α Syn and thereby identify novel drug-like small molecules that impact multiple pathogenic processes. Using a surface plasmon resonance high-throughput screen, in which monomeric α Syn is incubated with microchips arrayed with tethered compounds, we identified novel α Syn interacting drug-like compounds. Because these small molecules could impact a variety of α Syn forms present in the ensemble, we tested representative hits for impact on multiple α Syn malfunctions *in vitro* and in cells including aggregation and perturbation of vesicular dynamics. We thereby identified a compound that inhibits α Syn misfolding and is neuroprotective, multiple compounds that restore phagocytosis

impaired by α Syn overexpression, and a compound blocking cellular transmission of α Syn. Our studies demonstrate that drug-like small molecules that interact with native α Syn can impact a variety of its pathological processes. Thus, targeting the intrinsically disordered ensemble of α Syn offers a unique approach to the development of small molecule research tools and therapeutics for Parkinson's disease.

The sequential misfolding of α -synuclein (α Syn) into oligomers and fibrils is central to the pathogenesis of Parkinson's Disease (PD) and related neurodegenerative disorders termed synucleinopathies¹. Lewy bodies containing α Syn amyloid-like fibril inclusions are a hallmark neuropathological feature of these diseases². The severity of disease correlates with the progressive spread of aggregated α Syn in patients³, and α Syn misfolding is associated with toxicity in cell and animal models⁴. In addition, strong genetic evidence links α Syn to PD including gene duplications or missense mutations that cause rare early onset forms of PD^{5–7} and genetic association studies also link α Syn to sporadic PD^{8,9}. This combined neuropathological, biochemical and genetic evidence provides strong support implicating the misfolding and aggregation of α Syn as a key feature in PD.

Monomeric α Syn, as an intrinsically disordered protein (IDP), exists primarily as a dynamic ensemble of distinct interconverting conformations that have the ability to take on more structured forms under the appropriate cellular context^{10,11}. In particular, α Syn can take on more ordered forms upon membrane binding^{12–14}. Owing to this intrinsic dynamic character and the ability to populate other forms upon interaction, IDPs are involved in many key biological processes¹⁵, are vulnerable to aggregation and are susceptible to prion-like amplification of misfolded species and transmission between cells¹⁶. This propensity towards aggregation and spread is likely to underlie the association that IDPs have with a growing number of misfolding diseases, notably many neurodegenerative disorders¹⁷.

Small molecule binding to native states of globular proteins has been successfully used to block misfolding and aggregation¹⁸ most notably in the case of targeting transthyretin to treat systemic amyloidosis¹⁹. By contrast, targeting of IDPs such as native monomeric α Syn with small molecules has been challenging due to their inherent structural heterogeneity and the absence of persistent structural elements¹⁰. Yet, the dynamic nature of the monomeric form of α Syn also provides opportunity to impact multiple aspects of the protein. For example, small molecules interacting with native α Syn could protect and stabilize specific conformations present in the ensemble, which in turn could enhance or inhibit misfolding, or modulate cellular malfunction associated with α Syn overexpression.

In spite of the inherent challenges, we previously identified potential small molecule binders to α Syn using an *in silico* screen. We showed that one of these compounds, 484228, displayed protective activity in reversing α Syn over-expression mediated neurodegeneration and impairment of phagocytosis without impact on aggregation of the recombinant protein²⁰, thus supporting the notion that small molecules can target an IDP such as α Syn and in doing so modulate cellular malfunctions independent of inhibitory effects on aggregation in solution. Encouraged by the success of the *in silico* screen, we embarked on biophysical screens to identify compounds that bind to IDPs using a surface plasmon resonance (SPR) based assay in which compounds are tethered to the chip (high-throughput chemical microarray surface plasmon resonance imaging, HT-CM-SPR)²¹. HT-CM-SPR has been successfully applied for the identification of small molecule binders to globular proteins, providing starting hits for drug discovery^{21,22}. Remarkably, we successfully used HT-CM-SPR to identify small molecules retarding the aggregation of tau protein, another IDP that misfolds in neurodegenerative diseases²³.

Here we apply the HT-CM-SPR screening technology to α Syn, and in addition to searching for aggregation-blocking compounds, as we did in the tau screen, we search for compounds correcting additional disease-relevant malfunctions of α Syn. We report here the identification of novel compounds that interact with native α Syn. A subset of these compounds can rescue α Syn dysfunction by reducing α Syn aggregation. Others can restore vesicular dynamics impaired by α Syn overexpression, as reflected in phagocytic capacity, while a distinct compound can block α Syn cell-to-cell transmission, without direct impact on aggregation. The identification of small molecules reversing diverse malfunctions of α Syn indicates that differing conformations and associated malfunctions of the protein may be targeted by small molecule ligands.

Results

Identification of small molecule binders of α Syn by high-throughput chemical microarray surface plasmon resonance imaging (HT-CM-SPR) screening. Monomeric α Syn was screened against a library of small molecules containing 91,000 lead-like and 23,000 fragment compounds immobilized on microarrays to identify small molecules binding to the protein using surface plasmon resonance (SPR) imaging (HT-CM-SPR)^{21,22} (Fig. 1a). An advantage of this chemical microarray paradigm is that α Syn is maintained in a soluble, monomeric, and label-free state enabling it to assume its heterogeneous conformational ensemble during screening. Moreover, the SPR-based detection is highly sensitive, which allows for identifying weak binding events²².

The monomeric nature of the α Syn was verified by dynamic light scattering (DLS), its native monomeric conformation ensemble by Nuclear Magnetic Resonance (NMR) and its purity by electrophoretic analyses (Supplementary Figs S1–S3). NMR H¹-N¹⁵ HSQC analyses compared the commercially generated α Syn protein used in the screen to that prepared in-house using standard protocols for preparation of monomeric ensembles of α Syn and they showed identical spectra (Supplementary Fig. S2). To verify the monomeric nature of α Syn in the screen, DLS analyses were performed on α Syn preparations under screening conditions and in parallel for each library screening experiment. α Syn stock solutions were shown to be free of aggregates with negligible (<0.1%) amounts of oligomers present. α Syn in screening buffer subjected to three-hour long incubations, the maximum amount of time used during screening, remained monomeric (Supplementary Fig. S3). In addition, there was no evidence of increasing SPR signal during the three-hour screening, as would have been seen had the α Syn been

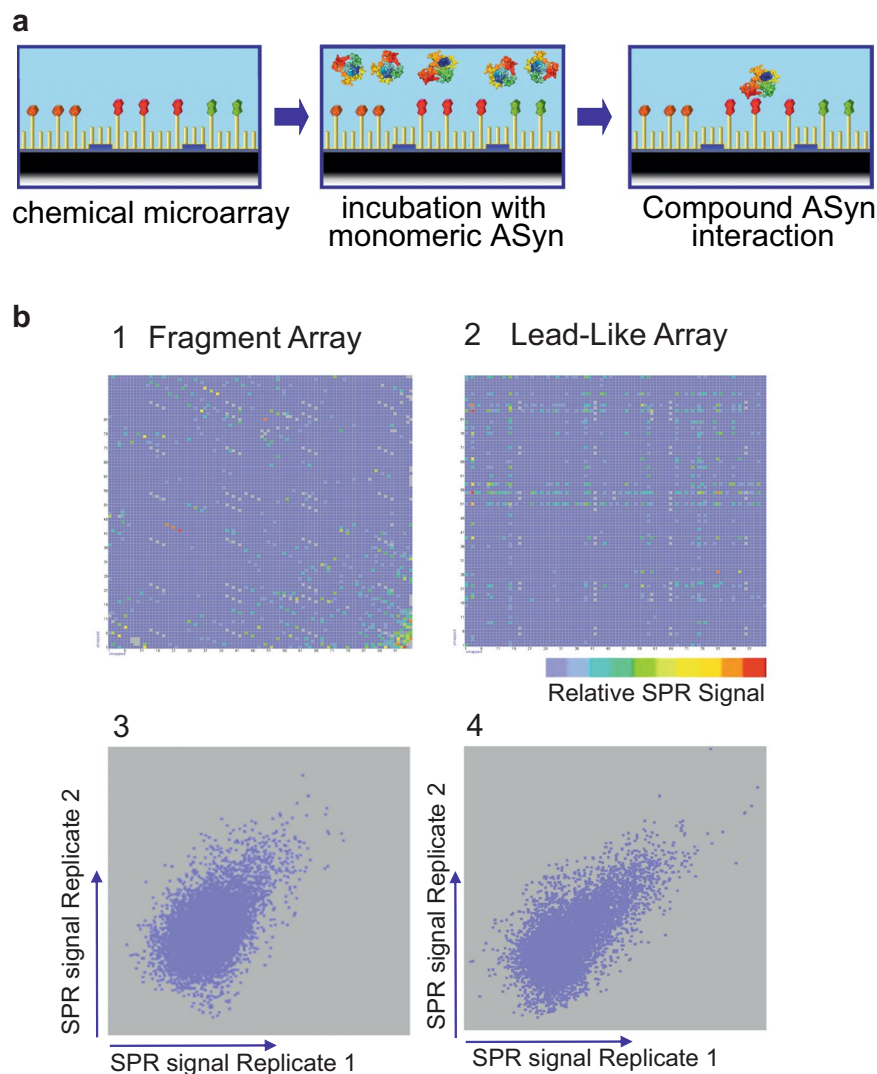

Figure 1. HT-CM-SPR Screening of α Syn. **(a)** The HT-CM-SPR process: Monomeric α Syn analyte floats over the array surface in screening buffer to allow binding events to occur. SPR imaging enables the detection of binding events. **(b)** SPR Test Screening Results: The upper two panels show images of color coded SPR signals obtained during HT-CM-SPR of α Syn under optimized screening conditions against individual representative microarrays comprised of (1) a fragment microarray containing 3,070 fragments (out of 23,000 fragments present in the entire screened NovAliX chemical microarray library) spotted in triplicate along a diagonal and (2) a lead-like microarray of 9,216 lead-like compounds (out of 91,000 lead-like compounds present in the entire screened NovAliX chemical microarray library) individually spotted. The lead-like compounds are derived from combinatorial synthesis approaches with each row and column on the microarrays consisting of a common fragment in combination with 96 other diversities. In these fingerprint representations of the microarrays each spot is representative of a separate small molecule tethered to the array with the location on the chip reflected by the location on the fingerprint and the color representing the intensity of signal for that spot (color ranging from low shifts (blue) to high (red) signals). The lower panels 3 and 4 show reproducibility of duplicate screening experiments for chemical microarrays shown in panels 1 and 2. The reproducibility of these subsets of compounds is representative of results obtained for the entire NovAliX chemical microarray library with (3) triplicates of 3,070 fragments and for (4) individual 9,216 lead-like compounds immobilized. In these scatter plots, each spot compares the signal strength measured for the microarray samples in each of the independent array experiments with signals from one replicate experiment indicated on the Y-axis and that of the other experiment represented on the X-axis.

oligomerizing on the microchip. Thus, the detected SPR signal reflects the interactions between monomeric α Syn and the immobilized library.

Microarrays were incubated with α Syn under optimized conditions, imaged and subjected to hit selection as described in the Supplementary Information. Briefly, chips were incubated with monomeric α Syn under conditions optimizing signal and shown to maintain α Syn in its monomeric state (Supplementary Fig. S3). Figure 1b shows representative examples of α Syn SPR fingerprint analyses for two individual microarrays selected from the

Table 1. Physico-chemical properties of selected hit compounds. Analysis of the physico-chemical properties for the 152 representative hit compounds selected from the initial pool of 563 hits identified by the HT-CM-SPR screen of monomeric α Syn, as well as for the 65 resynthesized compounds. For immobilization to the chip surface all library compounds were tethered to the chip via a linker group R. In order to calculate the ClogP, H-bond acceptor count, H-bond donor count, the count of rotatable bonds and TPSA (topological polar surface area) for the 152 array hits, this R-group was virtually replaced by a carbon. For the calculation of the molecular weight (MW) and Heavy Atom Count (HAC) the R group was replaced by a hydrogen atom. For the 65 resynthesized compounds, the linker group R at the attachment point at the compound was synthetically replaced by other groups such as methyl groups, which are included in the calculation of all properties.

13 arrays that comprise the library. Shown are examples of a microarray containing fragments (panels 1 and 3) and another microarray containing lead-like compounds (panels 2 and 4). Panels 1 and 2 show imaging analyses of the microarrays with each spot reflecting the position of a tethered small molecule sample on the array and the color of that spot reflecting the signal upon incubation with α Syn. On chips containing lead-like compounds based on combinatorial synthesis approaches, related library compounds are arrayed in rows and columns, with one unique copy per compound species present per physical microarray. Hence hit series with multiple members interacting with α Syn generated array patterns of colored lines as shown in Fig. 1b panel 2. Such patterns can be used to identify hit series with multiple related compounds interacting with the target protein. Some chips also contain many singleton compounds for diversity in the library, so these generated hit patterns of single colored spots. The low molecular weight fragment library compounds, in contrast, were spotted in triplicates and therefore triplicate signals of α Syn interacting fragment hit compounds can be observed (Fig. 1b panel 1). Each array was assayed in duplicate during the screen. Figure 1b panels 3 and 4 show scattergrams that illustrate the reproducibility of the raw SPR signals for each spotted sample in two independent repetitions for a representative of each type of microarray (the same representative microarrays shown in panels 1 and 2). The reproducibility of these subsets of compounds on the chosen microarrays is representative of results obtained for the entire library. Averaged SPR signals from replicate samples were filtered to remove outliers and JARRAY, NovAliX's proprietary software routine, guided hit selection.

The screen identified 563 immobilized hit compounds interacting with α Syn, corresponding to a hit rate of 0.49%. The signal strength and hit rate generally were lower than that of previously screened globular proteins, but comparable to those obtained for our screen on the tau protein with HT-CM-SPR²³. While for globular proteins of similar molecular weight to that of α Syn, signal to noise ratios of more than 10 were regularly obtained, for α Syn the signal to noise ratios ranged between 2 and 5. Nevertheless, as for the tau screen, hit compounds could be determined. Overall, hits included compounds which could be grouped into various compound classes and a number of structurally independent singleton compounds. We selected 152 representative hits out of the initial set of 563, based on parameters such as physicochemical properties, molecular weight, SPR signal strength, structural diversity, chemical tractability and overall attractiveness for drug development. This selected set contains structurally diverse and different lead-like and fragment-like compounds. Interestingly, a high number of positively charged and structurally different amines were identified. The molecular physicochemical properties indicate tractability for drug development of this compound set (Tables 1 and S1). For further analysis of untethered hit compounds in follow-up assays, a subset of 65 compounds was selected for synthesis. This subset, the properties of which can also be found in Table 1, was chosen to cover chemical space of each structural class identified from the screen including singletons. All 65 compounds were synthesized devoid of the chemtag linker moiety, which was replaced with appropriate atoms/groups.

Multiple hit compounds inhibit α Syn fibril and oligomer formation and one blocks cellular neurotoxicity.

Misfolding of α Syn can result in the formation of toxic oligomers and amyloid fibrils²⁴. Binding of small molecules to α Syn could block or enhance the transition of α Syn to β -sheet rich soluble oligomers and or fibrils depending on what conformation or sites are bound. We therefore screened the synthesized hit compounds in an α Syn aggregation assay, in which the fibril formation of the protein is monitored by Thioflavin T (ThT) fluorescence. Two compounds (576755 and 582032) are shown here which inhibit the fibrillization of α Syn (Fig. 2a). Shown in Fig. 2a for these compounds are examples of three separate experiments with the average of quadruplicate samples at each time point. Statistical analyses as described in Supplementary Information were used to determine significance of differences between compound and DMSO control. For the experiments summarized in Fig. 2a a significant difference from DMSO control was found for compound 576755 in 3 out of 3 experiments,

Figure 2. Multiple HT-CM-SPR screening hit compounds block α Syn misfolding. **(a)** The impact of compounds on α Syn fibrillation activity, monitored by thioflavin T fluorescence, is shown. Examples are shown of three independent experiments for compounds tested at 300 μ M in the α Syn fibrillation assay along with 0.5% DMSO control. Boxed numbers indicate the ratio of experiments demonstrating significant impact. Statistical analyses, (see Supplementary Information) indicate significant differences (p -value < 0.05) from DMSO for 576755 in 3 out of the 3 shown experiments, and for 582032 in 2 out of 3 experiments. Compound 573434 has no impact on α Syn fibrillation in a biochemical assay. **(b)** Anti-fibrillation activity of compound 576755 at 300 μ M is demonstrated in both the standard (left) and seeded-aggregation (right) assays in which α Syn protofibrils are added at the initiation of the assay. **(c)** A dose response for compound 576755 in the fibrillation assay shows activity as low as 25 μ M. For all fibrillation figures each data point represents the mean \pm SEM of quadruplicate wells. **(d)** Dose response of anti-oligomerization activity of three compounds

are shown in a split Gaussia luciferase (GLuc) complementation assay executed as described in Methods. GLuc units are in arbitrary light units. The top panel shows the time course of inhibition by 576755 at multiple doses and the bottom panel shows the dose response and IC₅₀s of all three active compounds at $t = 24$ hours. (e) The impact on oligomerization for all compounds discussed in this manuscript are shown. GLuc units are normalized to the mean of DMSO control. Means \pm SD. are shown. (f) The anti-oligomerization activities of the three compounds identified in panel (d) are validated in a FRET based α Syn oligomerization assay executed as described in Methods. Compound structures are also shown in Supplementary Fig. S4.

and for compound 582032 in 2 out of 3 experiments with a trend to inhibition in the third experiment. Addition of compounds to α Syn monomer and ThT in the presence of preformed α Syn fibrils (Fig. 2b, seeded fibrillization) demonstrates that compound 576755 blocks fibril growth in this rapid and robust paradigm showing activity as early as 2 hours in the incubation (Fig. 2b, right panel). The slower time-course of the traditional (non-seeded) fibrillization assay run in parallel is shown in Fig. 2a. Compound 576755 shows near half-maximal anti-fibrillization activity at a substoichiometric concentration of 25 μ M (Fig. 2c) in the traditional fibrillization assay, in which α Syn is incubated at 70 μ M.

Compelling evidence supports pre-fibrillar α Syn oligomers as the pathogenic species in disease. α Syn oligomers are directly toxic to cells²⁵, and mutations enhancing α Syn oligomer formation increase α Syn toxicity^{26,27}. We therefore screened our compound set for impact on biochemical and cellular α Syn oligomerization. Two novel biochemical assays were developed for α Syn oligomerization based on either bioluminescent complementation of Gaussia luciferase (GLuc) split tags or on FRET of small molecule tags (see Supplementary Fig. S5 and Supplementary Information). The oligomerization assays we report here are sensitive, quantitative and reproducible assays of early α Syn misfolding and the bioluminescent assay in particular has a good dynamic range (Supplementary Fig. S5). The 65 synthesized hit compounds were tested in the biochemical bioluminescent complementation assay at 100 μ M and three active compounds were identified (Fig. 2e), including the two compounds active in the fibrillization assay (Fig. 2d: 576755, IC₅₀ of 10.5 μ M, and 582032, IC₅₀ of 290 μ M) and an additional compound (573437, IC₅₀ of 104 μ M). The activities of all three compounds were verified in the FRET based α Syn biochemical oligomerization assay (Fig. 2f), demonstrating that the compound action was directed at α Syn and not the luciferase tags. The development of the novel oligomerization assays, which are much less variable than fibrillization assays, allowed us to identify the additional compound 573437 which most likely due to the variability of the fibrillization assay did not reach significance during the fibrillization testing.

Maximal concentrations of compounds not showing toxicity were tested in H4 neuroglioma cells for impact on α Syn cellular oligomerization using a bioluminescent protein-fragment complementation assay²⁸. The only compound that reproducibly reduced cellular oligomers was 576755 (Fig. 3a). Western controls show no significant change of cellular α Syn protein levels by 576755 (Fig. 3b, a trend to increase is seen). To test the effects of 576755 on α Syn-induced neurotoxicity, we used a primary midbrain culture model of PD²⁹. As a control, we first established that there is no detectable toxic effect on primary dopaminergic neurons exposed to 60 μ M 576755 alone (Fig. 3c). Transduction of the primary cultures with an adenovirus encoding A53T α Syn, a PD-linked genetic mutant found to form toxic oligomeric species more readily than the wild type protein^{5,30}, results in a 30–40% reduction in the number of TH-immunoreactive neurons (Fig. 3d). In contrast, transduction with a virus encoding the control protein LacZ has no effect on neuron viability³¹. Treatment of the primary midbrain culture with 576755 at 60 μ M, suppressed A53T α Syn neurotoxicity, and a trend towards a similar inhibitory effect was observed for cultures treated with the compound at 10 μ M (Fig. 3d).

Multiple hit compounds reverse α Syn mediated inhibition of vesicular dynamics. Elevated α Syn can interfere with the creation, localization, and/or maintenance of vesicle pools^{32,33}. We have demonstrated that α Syn overexpression impairs phagocytosis in H4 neuroglioma cells, in primary microglia isolated from α Syn transgenic animals overexpressing α Syn and in cells from human PD patients by blocking recruitment of vesicular components necessary to support a phagocytic response³⁴. We further reported that an α Syn binding compound derived from an *in silico* screen, 484228, restored normal phagocytosis in the face of ongoing α Syn overexpression²⁰. We thus tested whether the α Syn binding hit compounds found here could protect against this α Syn over-expression induced dysfunction. The synthesized hit compounds were screened first for cellular toxicity at ranges from 1 μ M to 100 μ M. 53 compounds, showing no toxicity at 1 μ M, in the absence of serum were subjected to further screening for their impact on phagocytosis in H4-neuroglioma cells overexpressing α Syn^{20,34} at two concentrations below that for which toxicity was seen. Seven compounds showed robust activity in reversing α Syn mediated inhibition of phagocytosis in H4-neurogloma cells in the initial screen. Five of these compounds were retested at 10 and 1 μ M and 100 nM concentrations (Fig. 4a). All compounds showed complete reversal at 1 μ M and two compounds (573418, 573419) showed complete reversal at 100 nM (Fig. 4a). Western analyses demonstrate that none of these compounds alters α Syn protein levels (Fig. 4b) and none of these compounds impaired α Syn oligomerization (Fig. 2e).

One hit compound blocks α Syn cellular transmission without apparent impact on misfolding. Lower-order α Syn oligomeric species and fibrils propagate their misfolded structure and transmit from cell-to-cell in a prion-like manner^{35–37}. We therefore tested selected compounds in a cellular model of α Syn transmission^{38,39}. Figure 5 shows that compound 573434 retards α Syn transmission both in B103 rat neuroblastoma cells using a co-culture paradigm (at the Gladstone Institutes; Fig. 5a) and as executed at a different institution in primary neurons using a separate chamber culture paradigm (at UCSD; Fig. 5b,d) with activity at 10 μ M 573434. 573434 has no observed impact on α Syn fibrillization nor oligomerization (Fig. 2a,e) and does not impact α Syn

Figure 3. Cellular activities of anti-aggregation compound 576755. **(a)** 576755 reduces α Syn oligomerization in H4 cells as measured by complementation of α Syn proteins with split luciferase tags executed as described in methods. Trace firefly luciferase co-transfected provides a normalization measure for transfection efficiency. 0.3% DMSO is present in all samples. Data are plotted as means \pm SD. Shown are representative results from 3 independent experiments. A reduction in cellular oligomerization by 576755 was determined by one-way ANOVA with Dunnett's post-test. **(b)** 576755 does not reduce on α Syn levels in H4 cells as determined by Western analyses (trend towards small increase seen). (Right) representative Western from one experiment of a merged image detecting actin and α Syn from H4 cells transiently transfected with vector control or α Syn containing N or C terminal split luciferase tags (SynGN + SynGC) and treated with 0.3 percent DMSO or 150 μ M 576755. The two α Syn bands correspond to different tags. Entire length of blot shown. Outline of full blot shown by black lines. (Left) α Syn was quantitated in 3 separate biological replicates. Samples were normalized to cells transfected with α Syn without drug treatment to allow comparisons between blots. There is no significant difference in α Syn levels in 576755 treated vs. untreated cells (100) as determined by one sample t test. Data are plotted as mean \pm SD. **(c)** 576755 is not toxic and **(d)** alleviates loss of dopaminergic neurons induced by the A53T mutant of α Syn. Primary rat embryonic midbrain cultures were non-transduced or transduced with adenovirus encoding A53T α Syn (+Ad SynA53T), in the absence or presence of 576755. The cells were then stained immunocytochemically for MAP2 and TH. Preferential dopaminergic cell death was assessed by evaluating the percentage of MAP2-positive cells that also stained positive for TH. Data are plotted as the mean \pm SEM. $n = 2-3$ for the neuron toxicity analysis and $n = 5$ for the reversal of α Syn toxicity. Shown are representative results from 5 independent experiments. Statistics used a one-way ANOVA with Tukey post-test after square root transformation of the data. * $p < 0.05$ where shown. *** $p < 0.001$. **** $p < 0.0001$. ns is not significant.

levels in the donor cells as measured by quantitative immunohistochemistry (Fig. 5c) and by Western analyses (Supplementary Fig. S6). Furthermore 573434 does not impact the secretion of α Syn from cells as determined by Western analyses (Fig. 5e). Thus, the mechanism of action of 573434 is not due to direct action on α Syn misfolding, nor on expression or excretion of α Syn.

Discussion

In a prior study we reported on a novel strategy to target the monomeric intrinsically disordered ensemble of α Syn by using a structure-based computational docking screening approach to identify small molecules predicted to bind to monomeric α Syn, and then testing their impact in diverse α Syn mediated biochemical and cellular assays. An advantage of this approach is its potential to identify compounds that have a variety of effects related to α Syn malfunction or misfolding. This effort identified one compound, 484228, which reversed the impairment of phagocytosis, dopaminergic neuronal loss and neurite retraction caused by overexpression of α Syn²⁰.

In order to expand upon this strategy, we applied a biophysical-based binding screen that detected the interaction between a small molecule and native monomeric α Syn, using SPR technology, an approach we have

Figure 4. Multiple HT-CM-SPR screening hit compounds alleviate α Syn mediated inhibition of phagocytosis in H4-Neuroglioma cells. H4 neuroglioma cells over-expressing α Syn from a tetracycline-inducible promoter were cultured for 24 hours with compound in the absence or presence of α Syn induced by tetracycline. After 24 hours of induction cells were (a) fed 4 micron beads for 90 minutes and a phagocytic index was measured by quantitating the amounts of engulfed beads on an imaging reader or (b) analyzed by Western blot to determine α Syn levels. (a) The phagocytic capacity was calculated by normalizing the indicated samples to the phagocytic capacity of un-induced cells not overexpressing α Syn (Tet off). Each point corresponds to a separate experiment denoting the average of 6 well replicates. Means \pm SD for the combined multiple experimental averages are shown. Control compound is 484228, identified in a prior *in silico* screen²⁰. $n = 2$ or 3 different experiments as shown. Significance was determined by ANOVA with Dunnett's correction. * $p < 0.05$, *** $p < 0.001$, **** $p < 0.0001$. ns is not significant. (b) Cells were untreated or treated with tetracycline to induce α Syn and treated with DMSO or compounds and analyzed by Western blot for actin and α Syn levels. Left: Representative Western blots of merged actin and α Syn signals of individual wells treated with DMSO or compounds. Image cut as shown to remove irrelevant samples. Entire length of blot shown. Outline of full blot shown by black lines. Right: Westerns from multiple replicates were quantitated and the α Syn band intensity was normalized to that of actin. Each data point is a separate well. No compounds showed significant impact on α Syn levels. Compound structures are also shown in Supplementary Fig. S4.

successfully used to identify anti-aggregation compounds for the tau protein²³. The current screen identified over 500 hundred small molecules interacting with α Syn. We further showed that some of these compounds could beneficially impact α Syn malfunctions observed not only in aggregation assays, as we had found for the previous tau protein screen²³, but also in multiple cellular malfunction assays. Our anti aggregation compound 576755 blocked cellular α Syn oligomer formation and protected dopaminergic neurons against α Syn toxicity. We found compounds similar to our reported 484228²⁰ that reversed the impairment of phagocytosis by α Syn, and we also found a different compound that blocks cell-to-cell transmission of α Syn. Further studies will be needed to establish whether these compounds interact with the different conformations of monomeric α Syn and/or higher-order assemblies. Overall, however, as we had anticipated, an expanded screen for compounds binding to monomeric α Syn yielded a variety of novel classes of compounds having different effects on α Syn mediated pathological processes providing a rich starting point for drug-discovery.

There is ample evidence that links α Syn misfolding and aggregation to the onset and progression of PD⁴⁰. It is still unclear, however, which conformations of misfolded α Syn contribute most to pathogenicity. Prior screens for compounds modulating α Syn aggregation have relied largely on screening in fibrillization assays, and many have yielded compounds that block aggregation in a non-specific manner mediated through polymeric self-stacked forms of the compounds^{41,42} or via reactive quinone formation⁴³ which complicates translation into effective

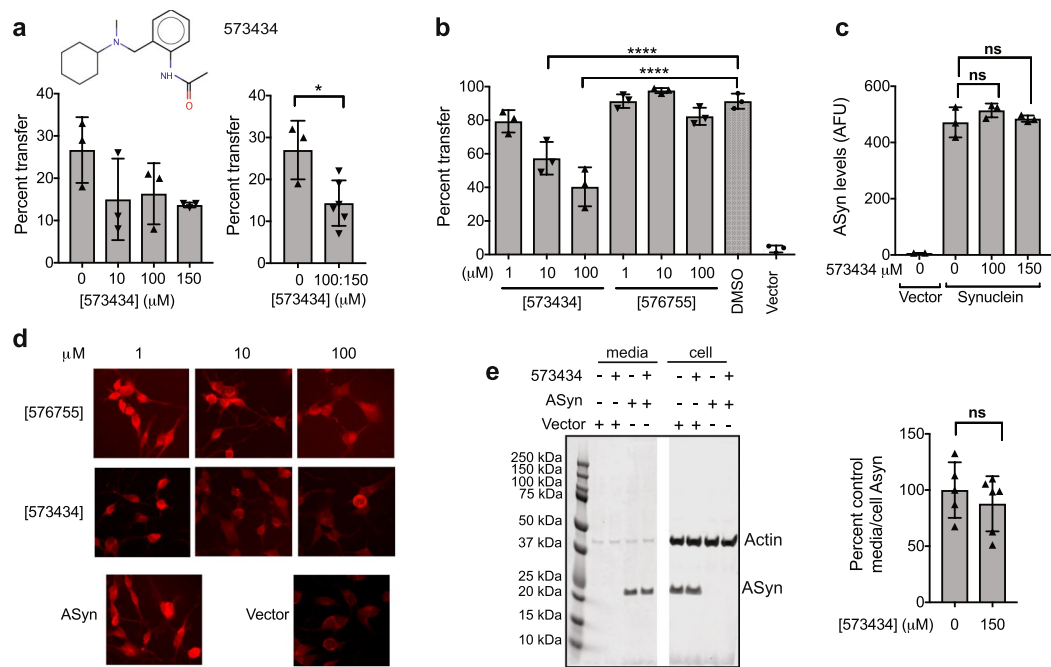

Figure 5. One HT-CM-SPR screening hit compound blocks cell-to-cell transmission of α Syn. **(a)** The impact of 573434 on transmission was tested on co-cultured donor and recipient B103 neuroblastoma cells and mean percentage of receiving cells with α Syn is shown. The same data are shown separating all compound doses (left) or combining 100 and 150 μ M (right). 3 coverslips/well per group, 10–15 pictures per coverslip, and 43–168 cell total per group were analyzed. Combined 100 and 150 μ M drug samples give statistically significant differences from untreated by unpaired t test ($n = 3$). **(b)** Donor and acceptor primary neurons were cultured in separate chambers of a Transwell and α Syn in acceptor cells was measured after treatment with 573434 or 576755. Vector control is lentiviral vector not expressing α Syn. 10 and 100 μ M 573434 retarded transmission whereas 576755 had no impact as determined by ANOVA with Dunnett's correction. **(c)** Total α Syn levels were determined from the fluorescent intensity from α Syn antibody (arbitrary fluorescence units, AFU) in the images used in panel (a). 3 coverslips per group, 8–11 pictures per coverslip, and 24–54 cell total per group were analyzed. 573434 does not impact overall expression of α Syn as determined by unpaired t test. **(d)** Representative images of α Syn transmission in primary neurons treated with 573434 and 576755. **(e)** Cells and media produced by B103 cells infected with control or α Syn-lentivirus and treated with DMSO or 150 μ M 573434 were analyzed by Western blot for actin and α Syn levels. Left: Western blot of both actin and α Syn proteins of duplicate wells. Image cut as shown to remove irrelevant samples. Entire length of blot shown. Outline of full blot shown by black lines. Right: the ratio of α Syn in the media to α Syn in the cell was quantitated from three separate experiments with duplicate wells ($n = 6$). α Syn levels in cells and media were normalized to actin levels in cells of that well and then further normalized to control (DMSO) sample on the same gel to allow for comparison between experiments. 573434 has no impact on the amount of α Syn secreted into the media. For all figures drug treated and control cells are in equivalent levels of DMSO (0.15 to 0.3%). Each symbol represents a single coverslip in a unique well. Mean \pm SD. * $p < 0.05$, *** $p < 0.001$, **** $p < 0.0001$, ns—not significant. Compound structure is also shown in Supplementary Fig. S4.

drugs. Although our most potent anti-aggregation compound, 576755, has quinone potential, two additional misfolding blocking compounds without this liability were found in this screen using novel oligomerization assays. The biochemical bioluminescent protein complementation α Syn oligomerization assay, in particular, is a highly useful and novel assay in that it is amenable to high-throughput screening and does not rely on shaking or detergents to accelerate α Syn misfolding as is the case for a recently published α Syn high-throughput oligomerization assay⁴⁴. The ability to identify anti-aggregation compounds through a fundamentally different screening paradigm - that of SPR-based screening using monomeric α Syn - allowed us to obtain alternative compounds inhibiting aggregation. This will potentially expand our repertoire of anti-aggregation compounds to include compounds of possibly novel and druggable mechanisms.

The role of α Syn in modulating vesicle dynamics in cells is well established^{33,45–48}, and there are links between α Syn toxicity and vesicular dysregulation³³. We have reported that phagocytosis, which involves both mobilization and extrusion of vesicles, is impaired by α Syn over-expression in cultured cells and *in vivo* in transgenic mice as well as in cells from Parkinson's patients³⁴ suggesting that this dysfunction is a relevant target for therapeutic intervention in PD. Our experience using 484228 as a control compound in scores of assays at high doses is that it never restored phagocytosis inhibited by α Syn overexpression beyond 80 percent of that in cells with endogenous α Syn levels. The compounds reported herein restore phagocytic capacity to 100 percent of control and thus are likely to act via mechanisms distinct from that of 484228. Thus, the identification of multiple drug-like compounds with different scaffolds reversing α Syn impairment of phagocytosis expands upon our earlier results with compound 484228.

A central role of transmission and propagation of misfolded α Syn in disease is widely accepted³⁷. Although antibodies to α Syn are being tested in the clinic to block pathogenic spreading⁴⁹, small molecules targeting IDP spread are limited to aggregation inhibitors and to a single pharmacological chaperone⁵⁰. The anti-fibrillation compound 576755 did not impact transmission, despite its ability to reduce cellular oligomers. This could be due to differing drug sensitivities in the cells used in these assays. Nevertheless, we have identified a different small molecule, 573434, which blocks the transmission of α Syn from one neuronal cell to another. This compound does not change overall α Syn levels, ruling out a non-specific impact on the vector. It furthermore does not impact the overall levels of α Syn secreted from the cells. In biochemical assays it impacts neither α Syn oligomerization nor fibrillation indicating a novel mode of action for this molecule. There remain a number of possible mechanisms including (1) reduction of overall uptake of α Syn into receiving cells or (2) reduction of levels of a subpopulation of α Syn that is preferentially taken up in receiving cells. For example, Danzer and colleagues have shown that only the fraction of extracellular α Syn that is packaged into exosomes in the media is transmitted into receiving cells^{51,52}. Levels of this specific α Syn pool could be reduced by 573434. Further studies are needed to elucidate an exact mechanism of action for this compound.

The high-throughput approach described here may also be applied to other IDPs. Indeed, in a related study, we applied HT-CM-SPR screening for small molecules interacting with monomeric full-length tau, which resulted in the discovery of a variety of compounds which were able to reduce the aggregation of tau *in vitro* and in a cell model²³. Hence, these studies add to the accumulating evidence that small molecules can bind to IDPs, such as α Syn²⁰, tau^{23,53} and the A β peptide⁵⁴, despite their overall lack of persistent 3D structures.

In conclusion, these results support the notion that the dynamic monomeric solution state of α Syn can be successfully targeted by drug-like small molecules to reverse PD relevant dysfunctions. Our identification of small molecules impacting multiple types of α Syn malfunction demonstrates that targeting α Syn with screens employing ensembles of predominantly monomeric protein offers a rich and effective opportunity for drug discovery. We thus anticipate that this approach will be useful for the development of small molecule therapeutic candidates for Parkinson's disease and other diseases associated with IDP misfolding.

Methods

Additional details are in Supplementary information.

SPR screening of monomeric α Syn. The binding of α Syn was evaluated on a set of 96 control ligands of defined physical chemical properties in order to optimize buffer composition, ligand surface density and α Syn concentration. Minimum background and maximal total signal were obtained using 900 nM α Syn protein in 25 mM Tris and 100 mM NaCl, pH 7.4. α Syn at 10x that of screen concentration was predominantly monomeric as measured by DLS (>99.9%, see Supplementary Information). Freshly diluted α Syn in screening buffer was centrifuged through a 100kD cut-off filter, before incubation at room temperature on the arrays for up to 3 hours. Duplicate chips were run, with unique samples for the lead-like library and triplicate samples for the fragment library. Multiplicate SPR signals were averaged per compound. Compounds with standard deviation more than 0.5, or for which the purity before spotting or the saturation per spot was less than 80 percent were discarded.

Fibrillation assays. Prior to each aggregation assay, purified α Syn at 5 mg/mL was treated with 6M guanidine and dialyzed 36 hours in a 3500 MW cutoff Slide-A-lyzer with three changes of 20 mM sodium phosphate and 100 mM NaCl pH 7.4 buffer. α Syn was centrifuged at 130,000 g for 40 minutes in a Beckman Ultracentrifuge to remove seeding species and supernatant used for assays. For initial testing, compound was diluted to appropriate concentrations in 0.5% DMSO and controls contained equivalent DMSO concentrations. Assay samples contained 20 μ M Thioflavin T, filtered through a 0.45 μ m Acrodisc filter prior to each assay, 70 μ M α Syn in 20 mM sodium phosphate and 100 mM NaCl pH 7.4. One teflon bead, (0.125" PTFE, Grade 2 polished) was in each well of a 96 well black with clear bottom assay plate (Corning) in a total volume of 500 μ L. The plate was sealed with Mylar and parafilm, placed at 37 °C in a Tecan F200Pro Plate Reader and shaken at an amplitude of 6 mm for 120 hours continuously except for a brief time during reading of the plate. Thioflavin T fluorescence was detected by excitation at 440 nm and reading emissions at 485 nm each 60 minutes throughout the assay. To generate α Syn seeds for the seeding assays, α Syn at 10 mg/mL was incubated with stirring at 43 °C for 24 hours followed by exhaustive sonication. 1% (by mass) of seeds were added to the fibrillation assay. Samples were plated in quadruplicate, and the replicates averaged for each experiment for plotted data. Data were analyzed in Excel using XL-fit sigmoidal model #600.

Biochemical α Syn oligomerization assays. For the split Gaussia luciferase (GLuc) oligomerization assay 10 μ M each of α Syn-GLuc1 and α Syn-GLuc2 (see Supporting Information: N-terminal or C-terminal fragment of GLuc fused to the C-terminus of α Syn) were incubated in a buffer containing 1 mM MgCl₂, 1 mM ADP, 50 mM Na₃PO₄, 0.02% NaN₃ and 1 mM DTT at pH 7.4 at 37 °C in a thermal cycler (BioRad DNA Engine PTC-200). In some cases, when specified, the samples were incubated with shaking in an incubator at 37 °C. At 0, 6, 12, and 24 hours of incubation GLuc activity was quantified using the BioLux Gaussia Luciferase Assay Kit (NEB) according to the manufacturer's instructions with luminescent detection on a SpectraMax M5 Microplate Reader (Molecular Devices) using a 5 minute delay after the addition of substrate and 3 seconds of integration time.

For the FRET oligomerization assay, 10 μ M each of α Syn-Q-(Position#)C-Cy3 (donor) and α Syn-Q-(Position#)C-Cy5 (acceptor) in PBS (pH 7.4) were dispensed into black/clear bottom 384-well plates (Greiner) using a Mantis liquid handler (Formulatrix). The plate was sealed with AbsorbMax film (Sigma-Aldrich) and incubated at 37 °C. The FRET between donor and acceptor was measured on a SpectraMax M5 Microplate Reader (Molecular Devices). An excitation wavelength of 525 nm for α Syn-Cy3 (donor), and emission wavelengths of 570 nm and 670 nm for α Syn-Cy3 (donor) and α Syn-Cy5 (acceptor) respectively were used. The plate reader PTM sensitivity

was set to medium and assays executed without mixing. The signals were read at 10 minute intervals for 99 hours at 37°C. Efficiency of FRET was calculated as follows: $E_{\text{FRET}} = I_{\text{Acceptor}}/I_{\text{Donor}}$ in which I_{Acceptor} is acceptor emission intensity, I_{Donor} is donor emission intensity.

Cellular α Syn oligomerization assay. H4 neuroglioma cells (HTB-148; ATCC) were passaged in DME containing 10% fetal calf serum (FCS). They were plated into 10 cm dishes at 7.5×10^5 cells per dish and the following day transfected with DNA and Fugene (Promega, Madison, WI) according to the manufacturer's directions at a ratio of 3:1 with 7 μ g each of Syn-Luc1 (S1) and Syn-Luc2 (S2) plasmids⁵⁵ (also referred to as syn-hGLuc(1) and syn-hGLuc(2)⁵⁵ respectively, kind gifts from Dr. Pamela McLean) and 3 μ g of red firefly expressing plasmid (pCMV-Red firefly Luc, ThermoFisher, Waltham, MA) per dish. S1 and S2 plasmids express α Syn containing split Gaussia luciferase with either the N-terminal fragment (S1) or C-terminal fragment (S2) attached to the C-terminus of α Syn. After 24 hours, the DNA containing media was removed and cells were fed fresh DME media containing 10% FCS. The following day, cells were plated into polyD-Lysine coated clear bottom white well 96 well plates at 1.5×10^4 cells per well in Opti-MEM without phenol red with penicillin and streptomycin. After 4 hours cells are treated with drugs and incubated for 20 hours. Gaussia luciferase activity was measured in the dark 0.1 sec after injection of 100 μ l/well of 40 mM coelenterazine, substrate (NanoLight, Pinetop, AZ) using a 2 second integration on a Veritas Microplate Luminometer (Promega, Madison, WI). The cells were subsequently assayed for red firefly activity using the ONE-Glo™ Luciferase Assay System kit (Promega, Madison, WI) on a Spectramax M5 (Molecular Devices, San Jose, CA) plate reader as a normalization measure. 100 μ l of media were also assayed for red firefly activity. The impact of compounds on H4 cell toxicity was assayed using the CytoTox-Glo kit (Promega, Madison, WI).

Phagocytosis assay. A human neuroglioma H4 cell-derived cell line stably over-expressing α Syn from a tetracycline inducible promoter²⁰ was grown in serum-free X-VIVO media (Lonza Group, Basel, Switzerland). Cells were seeded in 96-well plates at 100 K cells per well. The next day, compound was added along with 5 μ g/ml tetracycline to induce α Syn overexpression. Cells were cultured overnight and the next day were fed 4 μ M red fluorescent beads (In Vitrogen, Carlsbad, CA) for 90 minutes at a cell-to-bead ratio of 1:10. Plates were gently washed with 100 μ l/well media twice, fixed and stained with HEMA3 (Thermo Fisher, Waltham, MA). Plates were dried overnight and read on an ArrayScan (Thermo Fisher, Waltham, MA). As the HEMA3 stain absorbs light, the internalized beads are less fluorescent than the outside beads. Tet/non-tet and 484228 samples were run on each plate.

Transmission assay. Lentivirus was made from the pLV- α Syn vector (LV- α Syn)⁵⁶ expressing his tagged α Syn or control green fluorescent protein vector (LV-control) as described³⁸. Titers were determined by P24 protein ELISA (primary neuronal experiments) or quantitative PCR of genomic DNA using transducing units of virus expressing green fluorescent protein titrated on HEK293 cells serving as a normalizing control (rat B103 experiments). Rat B103 neuroblastoma cells (from David Schubert, The Salk Institute) were grown in DMEM with 10% FBS at 37°C in 10% CO₂. Cryopreserved mouse cortical neural stem cells (MCNS) (MilliporeSigma, Burlington, MA) were grown according to manufacturer recommendations. α Syn transmission between cells was done using the methods described^{38,39} in one of two ways: (1) B103 neuronal cells: donor B103 neuronal cells plated in 6 well plates at 250,000 cells per well were incubated with LV- α Syn or LV-control at an MOI of 20 for 48 hours. B103 acceptor cells were labeled with the 595-Qtracker labeling kit (Life Technologies, Carlsbad, CA) according to the manufacturer's protocol. Donor and acceptor cells were trypsinized and replated together in a 12 well plate at 50,000 cells/well each on polyL coated coverslips. 4 hours post plating drugs were added. After 48 hours of co-incubation cells were fixed in 4% paraformaldehyde (PFA). Coverslips were stained with Syn1 antibody (BD Franklin Lakes, NJ) at a dilution of 1/500 and imaged on a Zeiss LSM 880 laser scanning confocal microscope and the percentage of receiving cells positive (cutoff of 10 standard deviations above negative control) for α Syn calculated by using ImageJ. Total α Syn levels were quantitated on the same images quantitating total fluorescence intensity from the Syn1 antibody using ImageJ. (2) MCNS neurons: Donor MCNS neurons were infected with LV- α Syn at a MOI of 20 for 48 hours, trypsinized and replated in 12 well cell culture inserts containing a 0.4 μ m PET membrane (Thermo Fisher, Waltham, MA) at 50,000 cells/well. Acceptor MCNS were plated in the bottom chamber of the 12 well Transwell plate at 50,000 cells/well on a poly-L-lysine coated glass coverslip. The 0.4 μ m filter, allows passage of secreted proteins but restricts direct cellular contact. 4 hours post plating, drugs were added. Cells were co-incubated for 48 hours and fixed with PFA, followed by immunocytochemical analysis.

Statistical analysis methods. Methods for the analyses of compound activity in the synuclein fibrillization assay are in Supplementary Information. Other statistical analyses were run using GraphPad Prism software as described. Multiple samples were compared using one-way ANOVA with Dunnett's and an alpha of 0.05. In analyzing percentage cell viability data by ANOVA, square root transformations were carried out to conform to ANOVA assumptions, and Tukey's post *hoc* test was used for multiple comparisons³¹. In cases where two samples were used t tests with an alpha of 0.05 were used. General practice significance nomenclature was used (0.1234 (ns), 0.0332 (*), 0.0021 (**), 0.0002(***), <0.0001(****) unless otherwise indicated.

Compound analyses and handling. The 65 resynthesized compounds chosen for testing in functional assays were verified as the indicated structure and of sufficient purity by ¹H-NMR and by liquid chromatography and mass spectrometry analyses (LC-MS). These 65 compounds were at least 85% pure, with most over 95% pure. The active compounds were all over 90% pure. Additional information including the LC-MS determined purity and ¹H-NMR peaks for the 9 active compounds described herein are listed in Supplementary Information.

For all compound testing, controls are run in the equivalent amount of DMSO.

Associated content. Supplementary Information includes detailed data with expanded description and expanded methods.

Data availability

The human neuroglioma H4 cell-derived cell line stably over-expressing α Syn from a tetracycline inducible promoter²⁰ can be obtained after signing Material Transfer agreements with Imago Pharmaceuticals (bd@imago-pharma.com) and Prothena Biosciences Inc (331 Oyster Point Boulevard South San Francisco, CA 94080, U.S.A. +1 650 837 8550). B103 neuroblastoma cells are available from Dr. David Schubert (schubert@salk.edu) with Material Transfer agreement from The Salk Institute (10010 N Torrey Pines Rd, La Jolla, CA 92037).

Acknowledgements

This manuscript is dedicated to Dale Schenk, who was an inspiring and visionary leader⁵⁷. We are grateful to Andrei Konradi and Al Garofalo for assistance in selecting compounds, to Paul Beroza and Ali Ozkabak for compound database management, to Kari Callaway for compound solubility testing and to Kari Callaway, to Karin Regnstrom and Donald Walker for helpful discussions. We are grateful to Pamela McLean and Simon Moussaouf for the S1 and S2 plasmids and advice on developing the cellular oligomerization assay, to Anthony L. Fink and Katerina Levitan for assistance in developing the high throughput synuclein fibrillization methods to Alexander Buell for sharing his seeded synuclein fibrillization methodologies. We further thank the Gladstone Histology and Light Microscopy Core for use of the confocal microscope. The research carried out at NovAliX (originally Graffinity Pharmaceuticals) and the University of Cambridge was supported by Elan Pharmaceuticals. Research at UCSF and the Gladstone Institutes was supported by and the National Institute of Neurological Disorders and Stroke of the National Institutes of Health under award number R21NS092897 (LM). Additional support was provided by R01 grant NS049221 and by a grant from the Branfman Family Foundation (J.-C.R.). We are particularly grateful to the late T. Gary Rogers and the Rogers Family Foundation for their support of this work (LM, DAA). DAA is also supported by the Howard Hughes Medical Institute.

Author contributions

Designed and performed research, analyzed data on HTS screen (T.N., H.-D.J., D.S., R.S., I.O., X.-H.C., B.S., J.P.A. and G.T.), designed and performed research, analyzed data on biochemical fibrillization testing (N.C., C.W.B., J.C., M.J., S.B. M.B. and W.H.), designed and performed research, analyzed data on biochemical oligomerization testing (J.T., D.A.A. and L.M.), designed and performed research, analyzed data on cellular oligomerization testing (A.B., P.N., M.T., J.T. and L.M.), designed and performed research, analyzed data on neurotoxicity testing (M.T., J.-C.R., B.S., E.M. and L.M.), designed and performed research, analyzed data on phagocytosis testing

(S.G., J.M. and T.Y.), designed and performed research, analyzed data on transmission testing (A.B., B.S., E.M. and L.M.), wrote the paper (L.M., G.T., D.A.A. and J.C.) designed research, supervised and analyzed data on all aspects (L.M., G.T. and D.S.). All authors reviewed the manuscript.

Competing interests

Drs Agard and McConlogue are owners of Dainton Biosciences, LLC, which has rights to the described compounds. No other authors have competing interests.
